# Introduction

The strong, weak and electromagnetic interactions are up to now described successfully within the Standard Model of elementary particles. This theory is based on a *local gauge principle* [1], with the gauge group

$$G_{loc} = \text{SU}(3)_c \times \text{SU}(2)_L \times \text{U}(1)_Y, \quad (1)$$

and it is essentially determined once the matter fields and their transformation laws under  $G_{loc}$  are specified.

The degrees of freedom are respectively the color for  $\text{SU}(3)$ , weak isospin for  $\text{SU}(2)$  and weak hypercharge for  $\text{U}(1)$ .

In particular, quantum chromodynamics (QCD) associated to the color group  $\text{SU}(3)$  is the currently accepted framework to describe strong interactions. The matter components are the quarks, which are described by spinor fields carrying three color indices and appearing in six flavors (up, down, charm, strange, top and bottom). The gluons are the vector bosons that mediate the interactions and, due to the fact that the gauge group  $\text{SU}(3)$  is non-Abelian, self-interactions exist, contrary to the situation in electromagnetism.

The formulation of QCD was the outcome of several years of investigations and discussions on experimental results.

The goal was to formulate a theory which is able to reproduce the two main features of strong interactions, asymptotic freedom and confinement, which are related to their properties in the high and low energy regimes, respectively.

The first step was the observation that the hadrons, which are the particles that participate in strong interactions, fall into multiplets that should reflect underlying internal symmetries. To express this fact in a concrete way, it was formulated the hypothesis that hadrons are composed of more elementary constituents with certain basic symmetries, which were called quarks [2, 3].

Asymptotic freedom was observed in deep inelastic scattering: at high energies the form factors in the cross sections lose their dependence on certain mass parameters; this scale invariance (also called *scaling*) was interpreted to mean that the constituents act as if they were free particles at extremely high energies. The most intuitive explanation of the scaling relation came from Feynman's *parton* model [4, 5, 6], where the proton was assumed to consist of point-like constituents. Later the partons were identified with the quarks on the basis of their quantum numbers.

Finally in 1973 Fritzsche, Gell-Mann and Leutwyler [7] proposed QCD as the non-Abelian gauge theory built from the  $\text{SU}(3)$  gauge group associated with the color symmetry.

The most direct experimental evidence that quarks must have an additional quantum number, the color, came from the measurements of the total cross section for the annihilation of electron-positron pairs in colliding beam experiments (SLAC, PETRA).

In the same year, it was shown [8, 9, 10] that non-Abelian gauge theory exhibits asymptotic freedom.

The appropriate framework to discuss this property is the renormalization group equation.

The insertion of quantum corrections leads to divergences in the evaluation of physical observables; these can be eliminated via renormalizing the theory by adding counterterms in the Lagrangian in a proper way. The consequence of the renormalization of a quantum field theory is that the coupling constant that appears in the Lagrangian becomes a *running coupling*. The so-called  $\beta$ -function quantifies the dependence of the coupling on the energy scale. Through the perturbative study of the  $\beta$ -function it was shown that at very high energies (or equivalently at small distances) the coupling becomes small, so that the quarks behave as free particles. In this regime one then expects that perturbative methods furnish reliable predictions for physical observables.

On the other hand, quarks have never been detected in isolation, but only as constituents of hadrons. From the theoretical point of view, this should correspond to the fact that all physical states are singlets with respect to the color group. In order to check whether this feature is contained in QCD, one can not apply perturbative methods, since the coupling is expected to be large at scales corresponding to the size of hadrons. It is however widely believed that this behavior is a consequence of quantum chromodynamics, although up to now no proof exists.

One of the strongest evidence for this to be true comes from lattice field theory. In 1974 Wilson proposed [11] a formulation of a gauge field theory on a discretized Euclidean space-time. In this framework, by using a *strong coupling expansion* it was possible to demonstrate that at sufficiently strong couplings, pure SU(3) lattice gauge theory exhibits color confinement: in the limit of large distances, the energy needed to separate a pair of quark-antiquark grows proportionally to the separation. Since then lattice field theory has been widely studied and became a powerful tool to investigate properties of strong interactions.

The natural framework to quantize the lattice theory is the path integral formalism; in this formulation the system takes the form of a classical four-dimensional statistical model. The matter fields are treated as classical stochastic variables assigned to the points of the lattice, while the gauge fields are associated to the links. In this analogy, the Euclidean action of the quantum field theory corresponds to the classical Hamiltonian of the statistical system and the mass of the lightest particle corresponds to the inverse of the correlation length.

The lattice furnishes a regularization of the theory by providing an ultraviolet cutoff proportional to the inverse lattice spacing and this is actually the only known non-perturbative regularization of quantum field theory.

The crucial question is whether the theory formulated on the lattice is well defined in the limit when the lattice spacing  $a$  is sent to zero. The physical continuum limit

corresponds to holding the values of physical quantities fixed while letting  $a \rightarrow 0$ ; the renormalization group equation describes how the parameters behave by changing the scale of the theory (in this case the lattice spacing). It turns out that the continuum limit is realized when the bare gauge coupling  $g_0$  is sent to zero. In the language of statistical mechanics this corresponds to a second order phase transition, where the correlation length in lattice units diverges. The basic concepts and definition of lattice gauge theory are reported in chapter 1.

An important advantage of the lattice formulation is that the path integrals which correspond to expectation values of physical observables can be computed numerically via Monte Carlo simulations. The idea is to generate samples consisting of a large number of field configurations according to the Boltzmann distribution and to evaluate the observables as sample average.

Since the first works by Creutz [12] on SU(2) this method was successfully applied to lattice pure gauge theories and in recent years to full QCD with two and three flavors of dynamical fermions; in this period, increasing precision and reliability due to theoretical improvement of the techniques has been accompanied by an enhanced computing power.

Due to the non-perturbative nature of the formulation, lattice field theory provides a very powerful tool to be adopted for the investigation of low energy features of QCD; the final goal is to test the Standard Model by evaluating from first principles physical quantities which one may compare to the experimental results.

Within this challenging task, lattice gauge theories can give important indications regarding basic questions related to strong interactions.

For example, it is expected that at high energies perturbation theory gives reliable estimates of physical quantities, but how high the energy must be is still subject of debate. The first evident problem of the perturbative expansion for QCD is that it is described by an asymptotic series: this means that after a certain order the perturbative expansion loses its predictive power.

Apart from this, a second problem is that the accuracy of the prediction is highly dependent on which renormalization scheme is adopted to define the observables. It turns out that different ways to subtract the divergences lead to different definitions of the running coupling in terms of which the perturbative series can behave quite differently.

The question whether perturbation theory is really applicable can be relevant in many practical cases; for example, the study of the perturbative evolution of deep inelastic scattering structure functions starting at a renormalization point below 1GeV was strongly debated. Another popular example is the experimental measurement of the strong coupling  $\alpha_s$  itself [13], which needs perturbation theory as theoretical input. The main phenomenological test of the applicability of perturbation theory is to check whether the determinations from different processes are compatible. From the experiments it is indeed difficult to study a process systematically as function of the energy.

What lattice gauge theory can do in this context is to furnish a non perturbative evaluation of the running coupling in order to compare the results with the predictions of perturbation theory and to establish at which energy one is allowed to apply

it.

Here one has to overcome a stringent limitation: the lattice spacing  $a$  can not be made arbitrarily small and on the other hand the physical extent of the system must be large ( $\gtrsim 1.5\text{fm}$ ) in order to approximate the condition of infinite volume. With this limitation, one currently reaches  $a^{-1} \sim 2\text{GeV}$  for  $N_f = 2$  flavors of dynamical quarks. A possible alternative has been proposed in [14], where one considers a finite size effect as the physical observable which defines a renormalized coupling. This method has been applied successfully in the framework of the Schrödinger functional scheme for the evaluation of the running coupling for  $N_f = 0$  [15, 16, 17] and  $N_f = 2$  [18, 19].

An important result was also the computation of the so-called Lambda-parameter in the theory with  $N_f = 0$  [15]: this quantity plays an important phenomenological rôle since it fixes the energy scale of QCD.

For this particular scheme the scale dependence of the running coupling has been found to be in good agreement with perturbation theory for  $\alpha < 0.3$ . These studies showed also that the perturbative scaling regime and the low-energy domain of the theory are smoothly connected, with no complicated transition region.

It is important to check these properties in many independent ways by comparing several quantities computed non-perturbatively with their perturbative prediction. An interesting quantity for this purpose is the static quark potential, which defines the energy of gauge fields in presence of two static color sources separated by a distance  $r$  and has been studied very intensively in the last years.

However, although many non-perturbative computations of this observables have been performed, there was up to now no convincing investigation in the short distance regime. With this goal we decided to evaluate the static quark potential in the  $N_f = 0$  case (for our purposes this means the pure Yang-Mills theory), for which it is possible to simulate large lattices; this allowed the investigation of the small distance region and the continuum extrapolation of the results obtained at finite lattice spacing.

At high energies, corresponding to small distances between the static quark-antiquark pair, the asymptotic freedom justifies the application of perturbative methods. After subtracting a constant part, the perturbative potential can be written in the form

$$V(r) = -\frac{4}{3} \frac{\alpha_{\bar{V}}(\mu)}{r}, \quad \mu = \frac{1}{r}, \quad (2)$$

which defines the running coupling in the so-called  $\bar{V}$  scheme.

This definition is restricted to perturbation theory since from the non-perturbative point of view the subtraction of the self-energy is not well defined.

Alternatively, one can define the coupling in the  $q\bar{q}$  scheme through the force

$$F(r) = \frac{dV}{dr} = \frac{4}{3} \frac{\alpha_{q\bar{q}}(\mu)}{r^2}, \quad \mu = \frac{1}{r}. \quad (3)$$

In perturbation theory, the potential is known at two loops [20, 21, 22]; however, the reliability of perturbation theory has been doubted at distances as short as  $0.1\text{fm}$ , and the presence of large non-perturbative terms has been argued [23, 24].

We started our investigation by constructing in the continuum a perturbative prediction for  $\alpha_{\bar{V}}(\mu)$  and  $\alpha_{q\bar{q}}(\mu)$ . By using the (non-perturbative) knowledge of the Lambda-parameter in units of the low energy scale  $r_0 \sim 0.5\text{fm}$  [25], it is possible to extract a parameter-free prediction for the running coupling via the renormalization group equation (RGE). The only ingredients that one needs are, for a given renormalization scheme, the corresponding Lambda-parameter and the coefficients of the  $\beta$ -functions. The Lambda-parameters in different schemes are connected exactly by one-loop relations and the  $\beta$ -function coefficients can be taken from the literature. With these ingredients we evaluated the 2- and 3-loops RG perturbative predictions for  $\alpha_{\bar{V}}(\mu)$  and  $\alpha_{q\bar{q}}(\mu)$ .

We want to stress that we are dealing with a single-scale problem and hence we expect that this is the best perturbative prediction, since there are no free parameters related to the energy scale to be fixed.

By analyzing the difference between the 2- and 3-loops behavior one can argue that for the  $\bar{V}$  scheme the perturbative expansion appears to be applicable only up to  $\alpha \sim 0.15$ , while for the  $q\bar{q}$  scheme the series is well behaved until  $\alpha \sim 0.3$ . This analysis gives already important indications on the quality of the perturbative prediction within these two different schemes. To clarify whether unexpectedly large non-perturbative terms are present in these observables was the strongest motivation of our computation.

First of all, we tried to give a reasonable phenomenological definition of a “large non-perturbative term”. We then evaluated the potential and the force on the lattice in the region  $0.05\text{fm} \leq r \leq 0.8\text{fm}$ .

The first step was to set the scale by specifying a dimensionful low energy observable in terms of which all other dimensionful quantities can be expressed. This observable must be chosen very carefully and must be evaluable with good precision.

In particular the length scale  $r_0 \sim 0.5\text{fm}$  [25], which is defined through the force, turned out to be a good choice. Due to the fact that we are interested in the short distance region, we decided to introduce a smaller reference scale  $r_c \sim 0.26\text{fm}$  also. Once renormalized quantities have been constructed, we performed the continuum extrapolation of the potential and the force; in this procedure we were also able to test the theoretical expectation on the leading lattice spacing errors to  $F(r)$ .

Finally we compared our continuum results with the perturbative predictions and we discussed the domain of applicability of perturbation theory for the different renormalization schemes.

As already mentioned, while perturbation theory describes the small distance regime, the long range properties are of non-perturbative nature. An intuitive picture of the confinement mechanism is given by an effective bosonic string theory [26]; a tube of color electric flux is formed between the quark and the antiquark and in the limit of large separation  $r$  one expects that the flux tube behaves like a string with fixed ends.

With this assumption, the static quark potential has the asymptotic expansion for large  $r$  [27, 28]

$$V(r) = \text{const.} + \sigma r + \frac{\gamma}{r} + \mathcal{O}\left(\frac{1}{r^2}\right), \quad (4)$$

where  $\gamma$  is an universal factor depending only on the dimensions of the system and  $\sigma$  defines the string tension.

This expression furnishes another parameter-free prediction of the potential and also in this case the non-perturbative results obtained via lattice calculations can be useful to validate this picture.

The problem here is that it is very difficult to evaluate the static quark potential at large distances with a good statistical precision; special numerical techniques are required and this was beyond the purpose of our work.

We compared however our results with eq. (4) also including a higher order term in the effective theory, which has been estimated in [29].

Chapter 2 is devoted to the static quark potential, the details of the lattice evaluation and the comparison with the predictions of perturbation theory and string model.

The second part of this work is dedicated to the study of the properties of different formulations of the gauge action on the lattice.

The simplest way to formulate a lattice gauge action is the one introduced by Wilson: one sums over plaquette terms, which are gauge invariant products of link variables along the smallest closed loop that one can build on a cubic lattice.

Within this framework one can show that the leading discretization errors that one introduces are of order  $O(a^2)$ .

Due to the practical limitations which prevent to study systems with very small lattice spacings and the impossibility in many cases to perform a continuum extrapolation of the physical observables, it would be highly desirable to work with a formulation in which the lattice artefacts are reduced. This problem is even more drastic in the fermionic action, where the leading discretization errors are linear in the lattice spacing.

For this reason in the last years there were big efforts in the formulation of both gauge and fermionic *improved* actions. The basic idea is to add appropriate combinations of *irrelevant* operators to the lattice action and to tune their coefficients such that the discretization errors are reduced. Using the language of statistical mechanics, the concept of *universality* ensures that the influence of irrelevant operators on the critical behavior is negligible and hence one recovers the desired physical continuum limit. At finite lattice spacing, the irrelevant operators govern the discretization errors, also called *scaling violations*<sup>1</sup>, associated to renormalized dimensionless quantities.

Several approaches were studied with this purpose. A popular one is based on the Symanzik picture [30] and has the goal to eliminate the leading lattice artefacts proportional to  $a$  for the fermionic action and to  $a^2$  for the gauge action.

This procedure has been applied to the gauge sector yielding the so-called Lüscher-Weisz action [31] and to the fermionic action by defining the so called Sheikholeslami-Wohlert (clover) action [32].

A different strategy is based on Renormalization Group (RG) considerations; a popular example is the Fixed Point (FP) action [33], formulated both for gauge and

---

<sup>1</sup>Note that in this context *scaling* is used with a different meaning than before and it is related to the behavior of physical quantities by approaching the continuum limit.

fermionic field.

Other examples are the Iwasaki [34] and DBW2 [35,36] gauge actions; the philosophy here is to perform blocking transformations to study the evolution of the couplings in a restricted parameter space, with the final goal to define a theory which lies close to the *renormalized trajectory*, where no lattice artefacts are expected to be present. In particular, these actions are restricted to a two-parameter space and they were constructed by adding rectangular ( $1 \times 2$ ) loops with a certain coefficient to the usual plaquette action.

The Iwasaki action has been used for instance by the CP-PACS collaboration [37] for an advanced computation of light hadron spectrum and RG improved gauge actions have been considered to be particularly suited for next simulations on Ginsparg-Wilson/domain wall fermions.

Before one starts to use extensively these alternative actions, it is important to investigate their properties, starting by checking the fundamental one which is the universality.

Moreover, the scaling behavior has to be tested for a possibly large number of observables in order to establish how efficient is the improvement.

We decided in particular to study the critical temperature for deconfinement,  $T_c$ , for DBW2 and Iwasaki action (chapter 3); by normalizing the quantity through the string tension  $T_c/\sqrt{\sigma}$ , it was observed [38] that even in the continuum limit the result obtained with Iwasaki action deviates from what was evaluated with the Wilson plaquette action.

A possible reason for this discrepancy could be a violation of universality, but we suspected that a more natural explanation is that the string tension is difficult to determine, and it is preferable to use the scale  $r_0$  to reliably set the scale in pure Yang-Mills theory.

In order to check whether this is the case, we evaluated  $r_0$  at the values of the critical couplings that can be found in the literature and built the renormalized quantity  $T_c r_0$  for the Iwasaki and DBW2 action.

In our evaluation we remarked that for these actions, and more generally for actions containing additional loop terms, the physical positivity is violated, as already pointed out in [39]. This fact spoils the applicability of the variational method, which in many cases is necessary to extract the physical observables. In appendix B the properties of the transfer matrix for improved actions are discussed and the presence of unphysical states is studied by investigating the location of the poles in the propagator at the lowest order of perturbation theory.

Finally we considered the glueball masses as additional quantities to test the properties of RG gauge actions (chapter 4).

Glueballs represent one of the most fascinating predictions of the gauge sector of QCD; the mass of the lightest ( $0^{++}$ ) glueball is moreover particularly promising to study the scaling behavior since several calculations with the Wilson action [40, 41, 42, 43] showed large lattice artefacts. We evaluated the  $0^{++}$  and  $2^{++}$  glueball masses for the Iwasaki and DBW2 actions for several values of lattice spacings by using an appropriate basis of operators from space-like Wilson loops up to length eight. Then we made use of our evaluation of  $r_0$  to form  $m_{0^{++}} r_0$  and  $m_{2^{++}} r_0$ .

There are several open questions that could be addressed and that have to be discussed in order to find an optimal combination of gauge and fermionic actions to obtain reliable results in future simulations of QCD. Some of them will be discussed at the end of chapter 4.

# Chapter 1

## Lattice gauge fields

Although QCD is the best candidate for a theory of the strong interactions, the quantitative information that can be extracted is still limited. It turns out that perturbation theory fails to reproduce many of the essential low-energy properties. The lattice formulation is one of the most elegant and powerful non-perturbative methods, and was originally introduced to investigate the confinement features. Its power comes mainly from the possibility to evaluate physical quantities “exactly” via numerical simulations, yielding a method to test whether QCD provides the correct framework for describing strong interactions. The QCD Lagrangian has six unknown input parameters: the coupling constant  $\alpha_s$  and the masses of the up, down, strange, charm and bottom quarks.<sup>1</sup> In the lattice regularization, once these free parameters have been fixed for example in terms of six measured hadron masses, then the (Euclidean) properties of the other particles made up of these quarks and gluons have to agree with experiments. Thus the lattice formulation allows the evaluation of physical observables *from first principles*. However, there are practical limitations, mainly due to the fact that the accessible lattice volumes and resolutions are restricted by the available (finite) computer performance and memory. In this chapter we will concentrate on the gauge sector of QCD and describe different lattice formulations of  $SU(N)$  gauge theory that will be used later for the extraction of physical observables.

### 1.1 Wilson action

The starting point for a lattice formulation of quantum field theory is the path integral formalism in Euclidean space-time [45], [46]. In this context it is possible to establish a useful analogy between Euclidean quantum field theory on a lattice and statistical mechanics, which is also the basis for numerical simulations. In the following we will consider pure  $SU(N)$  gauge theories on a 4 dimensional hypercubic lattice

$$\Lambda = a\mathbb{Z}^4 = \{x | x_\mu/a \in \mathbb{Z}\}, \quad \mu = 0, 1, 2, 3, \quad (1.1)$$

---

<sup>1</sup>The top quark is considerably heavier than the other quarks ( $m_t = 174.3 \pm 5.1\text{GeV}$  [44]), so that its bound states decay too fast to be detected. For this reason the top quark is not included here.

where  $a$  is the lattice spacing. The lattice introduces an ultraviolet cutoff and provides the only known consistent non-perturbative regularization of non-Abelian gauge theories. The Fourier transformation of functions on the lattice is periodic in momentum space with periodicity  $2\pi/a$ , therefore all momenta can be restricted to the first Brillouin zone

$$\mathcal{B} = \left\{ p \mid -\frac{\pi}{a} < p_\mu \leq \frac{\pi}{a} \right\}, \quad (1.2)$$

and the momentum cutoff is  $\pi/a$ .

An  $SU(N)$  lattice gauge field is an assignment of a matrix  $U(x, \mu) \in SU(N)$  to every lattice bond with endpoints  $x$  and  $(x + a\hat{\mu})$ , where  $\hat{\mu}$  denotes the unit vector in the positive  $\mu$  direction. Under a gauge transformation  $V(x)$  the link variables transform as

$$U(x, \mu) \rightarrow U'(x, \mu) = V(x)U(x, \mu)V^{-1}(x + a\hat{\mu}), \quad \forall V(x) \in SU(N). \quad (1.3)$$

A particular gauge-invariant object one can construct on the lattice is the trace of the product of link variables along a closed curve. These loops can be of arbitrary size and shape, and can be taken to lie in any representation of  $SU(N)$ . The simplest example is the plaquette  $W_{\mu\nu}^{1 \times 1}$ , a  $(1 \times 1)$  loop

$$W_{\mu\nu}^{1 \times 1}(x) = \text{Tr} \{ U(x, \mu)U(x + a\hat{\mu}, \nu)U^{-1}(x + a\hat{\nu}, \mu)U^{-1}(x, \nu) \}. \quad (1.4)$$

The action which has been proposed by Wilson [11] for pure lattice gauge theory is defined in terms of these plaquette variables

$$S = \beta \sum_x \sum_{\mu < \nu} \left\{ 1 - \frac{1}{N} \text{Re} W_{\mu\nu}^{1 \times 1}(x) \right\}. \quad (1.5)$$

Let  $A_\mu(x) = -ig_0 A_\mu^b(x)T_b$ , where  $T_b$  are the generators of the group, be a Lie algebra valued vector field defined on the lattice and let  $U(x, \mu) = e^{-aA_\mu(x)}$  be a smooth field; eq. (1.5) takes the form

$$S = -\frac{\beta}{4N} \sum_x a^4 \text{Tr} F_{\mu\nu}(x)F^{\mu\nu}(x) + \mathcal{O}(a^6), \quad (1.6)$$

where

$$F_{\mu\nu}(x) = \Delta_\mu^f A_\nu(x) - \Delta_\nu^f A_\mu(x) + [A_\mu(x), A_\nu(x)]$$

and  $\Delta_\mu^f f(x) = \frac{1}{a}(f(x + a\hat{\mu}) - f(x))$  is the lattice forward derivative. The leading term of eq. (1.6) for small  $a$  coincides with the Yang-Mills Euclidean action

$$S_{YM} = -\frac{1}{2g_0^2} \int d^4x \text{Tr} F_{\mu\nu} F_{\mu\nu} = \frac{1}{4} \int d^4x F_{\mu\nu}^a F_{\mu\nu}^a, \quad (1.7)$$

if we set  $\beta = \frac{2N}{g_0^2}$  and identify  $g_0$  with the bare coupling constant of the lattice theory; thus the Wilson action gives the desired classical continuum limit.

After having defined the field variables and the action, the next step to quantization

is to specify the functional integral. Given an observable  $\mathcal{O}[U]$  which is in general a gauge invariant function of the link variables, its expectation value is given by

$$\langle \mathcal{O} \rangle = \frac{1}{Z} \int D[U] \mathcal{O}[U] e^{-S[U]}, \quad (1.8)$$

where

$$Z = \int D[U] e^{-S[U]} \quad (1.9)$$

and  $D[U] = \prod_{x,\mu} dU(x,\mu)$  is the invariant group measure or *Haar measure*. In analogy to statistical mechanics,  $Z$  is called *partition function*. The high dimensional integral in eq. (1.8) can be evaluated by means of a (stochastic) Monte-Carlo method as an average over an ensemble of  $n$  representative gauge configurations

$$\langle \mathcal{O} \rangle = \frac{1}{n} \sum_{i=1}^n \mathcal{O}[U_i] + \Delta \mathcal{O} \left( \frac{1}{\sqrt{n}} \right), \quad (1.10)$$

where  $\Delta \mathcal{O}$  is the statistical error; the method represents an *exact* approach in the sense that the latter can in principle be made arbitrarily small by increasing the sample size  $n$ .

## 1.2 Continuum limit and improvement

Once one has evaluated a certain observable in lattice gauge theories, it remains the issue to understand how this is related to the continuum physical world. In order to obtain the theory in the continuum, the lattice spacing has to be sent to zero; at the same time, the cut-off goes to infinity and one has to construct renormalized physical quantities which remain finite in the continuum limit. In practice one has to compute the quantities of interest at different values of the lattice spacing  $a$  and to extrapolate the results to  $a = 0$ . An obvious limitation in this procedure is the fact that it is not possible to perform numerical simulations at arbitrarily small lattice spacings. In current calculations, one reaches  $a \sim 0.05\text{fm}$  for pure gauge simulations and the quenched approximation, and  $a \sim 0.1\text{fm}$  for full QCD.

Then the *improvement* of the lattice formulation turns out to be a very important topic, and in the last years there were a lot of efforts in this direction, both for the gauge and the fermionic action. The first requirement for an improvement program is a detailed theoretical understanding of the approach to the continuum limit, then extensive numerical studies are needed to confirm or disprove the expected behavior. The properties that a "good" improved action has to satisfy are first of all the reduction of the lattice artifacts, the better restoration of rotational and internal symmetries; in addition, for the study of topological properties, it would be desirable to work with a lattice action where small distance dislocations are excluded and only physical instantons are present. In the following sections several improvement procedures will be briefly explained.

### 1.2.1 The Symanzik program and the Lüscher-Weisz action

In 1983 Symanzik [30] suggested that the lattice theory can be approximated by a low-energy continuum effective theory, and the associated action can be written as

$$S_{\text{eff}} = \int d^4x \{ \mathcal{L}_0(x) + a\mathcal{L}_1(x) + a^2\mathcal{L}_2(x) + \dots \}, \quad (1.11)$$

where  $\mathcal{L}_0$  denotes the continuum Lagrangian and  $\mathcal{L}_k$ , with  $k \geq 1$ , are linear combinations of local operators of dimension  $4 + k$ . From the list of all possible such fields only those which are invariant under the symmetries of the lattice theory have to be included.

In the effective continuum theory, renormalized lattice fields are represented through effective fields of the form

$$\phi_{\text{eff}} = \phi_0 + a\phi_1 + a^2\phi_2 + \dots \quad (1.12)$$

The so called Symanzik improvement programme consists of removing lattice artifacts organized as a power series expansion in  $a$ , by adding irrelevant terms to both the action and the operators. For pure gauge theory the corrections begin at  $O(a^2)$ , since there are no dimension 5 operators. It turns out that there are only 3 gauge-invariant dimension 6 operators and, if the Symanzik approach is correct, these should be sufficient to cancel the  $O(a^2)$  effects in the Wilson action. The improved action for SU(3) then takes the form

$$S = \beta \sum_{i=0}^3 \sum_{\mathcal{C} \in T_i} c_i \left\{ 1 - \frac{1}{3} \text{Re} W_{\mathcal{C}} \right\}, \quad (1.13)$$

where  $\mathcal{C}$  are oriented paths belonging to sets  $T_i$ ,  $i = 0, 1, 2, 3$  of structurally equivalent curves, which are indicated in Fig. 1.1 respectively by (a), (b), (c) and (d)

$T_0$  = set of curves enclosing one plaquette;

$T_1$  = set of planar curves with perimeter  $6a$  enclosing two plaquettes;

$T_2, T_3$  = set of non-planar curves with perimeter  $6a$ .

Note that the first term corresponds to the usual plaquette action and the number of the other classes matches the number of independent operators of dimension 6. The coefficients  $c_i$  have to be fixed such that on-shell quantities do not have  $O(a^2)$  corrections; at the classical level, they can be easily determined yielding the following results [47], [48]

$$c_0 = \frac{5}{3} = 1 - 8c_1, \quad (1.14)$$

$$c_1 = -\frac{1}{12}, \quad (1.15)$$

$$c_2 = 0, \quad (1.16)$$

$$c_3 = 0. \quad (1.17)$$

In quantum field theory the coefficients are subject to radiative corrections; the coefficients  $c_i$  have to be determined non-perturbatively to fully eliminate the  $O(a^2)$

**Figure 1.1:** List of paths which contribute to the action eq. (1.13).

artefacts, and this has not been achieved yet. The 1-loop improved action goes under the name Lüscher-Weisz action [31] and has coefficients

$$c_0(g_0^2) = \frac{5}{3} + 0.2370g_0^2, \quad (1.18)$$

$$c_1(g_0^2) = -\frac{1}{12} - 0.02521g_0^2, \quad (1.19)$$

$$c_2(g_0^2) = -0.00441g_0^2, \quad (1.20)$$

$$c_3(g_0^2) = 0, \quad (1.21)$$

with leading corrections of order  $O(g_0^4 a^2)$ .

### 1.3 Renormalization group improved actions

In recent years an alternative improvement strategy based on renormalization group (RG) considerations was developed. In general a quantum field theory is defined over a large range of scales from low (relative to the cut-off) physical scale up to the cut-off which goes to infinity in the continuum limit. The goal of a renormalization group transformation (RGT) is to reduce the number of degrees of freedom by integrating out the very high momenta and taking into account their effect on the remaining variables <sup>2</sup>.

This can be achieved for example introducing a blocked lattice with lattice spacing  $a' = 2a$  and blocked fields as average of the original fields; integrating out the latter keeping the block averages fixed, one obtains a new action  $S'$  which describes the interaction between the block variables. The important observation is that the partition function is unchanged, so that the long-distance behaviour of the Green-functions is expected to remain unchanged as well. On the other hand, the lattice spacing is increased by a factor 2 and the dimensionless correlation length, which

<sup>2</sup>This is the Wilson approach to Renormalization Group [49]

represents the inverse mass of the lightest state in the theory, is reduced by a factor 2

$$\xi \rightarrow \frac{\xi}{2}.$$

In momentum space, performing this transformation is equivalent to integrate out all momenta between a given scale  $q/2$  and  $q$ .

In general, the new action  $S'$  will contain every possible interaction term, even if the original action  $S$  had a simple form. It is then useful to start with a general action of the form

$$S(\phi) = \sum_{\alpha} K_{\alpha} \theta_{\alpha}(\phi), \quad (1.22)$$

where  $\phi$  are the original fields<sup>3</sup>,  $\theta_{\alpha}$  are all possible operators (interactions) and  $K_{\alpha}$  the corresponding couplings. The transformed action  $S'(\chi)$ , where  $\chi$  are the blocked fields, is also expanded in terms of these operators

$$S'(\chi) = \sum_{\alpha} K'_{\alpha} \theta_{\alpha}(\chi). \quad (1.23)$$

A RGT can be seen as a motion in the coupling constant space:  $\{K_{\alpha}\} \rightarrow \{K'_{\alpha}\}$ . Under repeated RGTs a coupling constant flow (RG flow) is generated

$$\{K_{\alpha}\} \rightarrow \{K'_{\alpha}\} \rightarrow \{K''_{\alpha}\} \rightarrow \dots, \quad (1.24)$$

while the dimensionless correlation length is reduced at every step

$$\xi \rightarrow \frac{\xi}{2} \rightarrow \frac{\xi}{4} \dots \quad (1.25)$$

The physical theory is preserved under each RGT, and thus along the whole flow. There will be special points called *fixed points* (FP) defined by

$$\{K_{\alpha}^*\} \rightarrow \{K_{\alpha}^*\}, \quad (1.26)$$

where the theory reproduces itself under a RGT. Due to eq. (1.25), at a fixed point the correlation function must be 0 or  $\infty$ .

Now consider a point  $\{K_{\alpha}\}$  close to the FP  $\{K_{\alpha}^*\}$ , with  $\Delta K_{\alpha} = K_{\alpha} - K_{\alpha}^*$  small. Applying a RGT and expanding around  $\{K^*\}$  we have

$$\Delta K_{\alpha} \rightarrow \Delta K'_{\alpha} = K'_{\alpha} - K_{\alpha}^* = \sum_{\beta} \mathcal{T}_{\alpha\beta} \Delta K_{\beta} + O((\Delta K)^2), \quad (1.27)$$

with

$$\mathcal{T}_{\alpha\beta} = \left. \frac{\partial K'_{\alpha}}{\partial K_{\beta}} \right|_{K=K^*}. \quad (1.28)$$

Let us denote the eigenvectors and eigenvalues of the matrix  $\mathcal{T}$  by  $h_a$  and  $\lambda_a$  respectively:

$$\sum_{\beta} \mathcal{T}_{\alpha\beta} h_{\beta}^a = \lambda^a h_{\alpha}^a, \quad a = 1, 2, \dots \quad (1.29)$$

---

<sup>3</sup>In this example for simplicity we can use scalar fields defined on the lattice sites.

The eigenvectors  $h^a$  define the eigenoperators

$$h^a(\phi) = \sum_{\alpha} h_{\alpha}^a \theta_{\alpha}(\phi), \quad (1.30)$$

which define a new basis in terms of which the action can be expanded

$$S(\phi) = S^{FP}(\phi) + \sum_a c^a h^a(\phi), \quad (1.31)$$

where  $c^a$  are the corresponding coefficients and are called scaling fields. By analogy,  $h^a$  are called scaling operators.

Iterating the RGT, one obtains that the coupling  $c^a$  goes over  $(\lambda^a)^n c^a$  after  $n$  RGT steps. For  $|\lambda^a| > 1$  ( $|\lambda^a| < 1$ ) the coupling  $|c^a|$  is increasing (decreasing) under repeated RG steps. The corresponding interaction  $h^a$  is called relevant (irrelevant). For  $|\lambda^a| = 1$  the behavior of the operator (called marginal) is decided by higher order corrections in eq. (1.27).

These general ideas can now be applied to Yang-Mills theory; due to asymptotic freedom, the continuum renormalized theory is obtained as  $g_0 \rightarrow 0$  ( $\beta \rightarrow \infty$ ) in which limit the correlation length goes to infinity, the lattice spacing  $a \rightarrow 0$ , the resolution becomes infinitely good and the cutoff artifacts disappear from the predictions. Introducing an infinite dimensional coupling constant space,

$$S = S(\beta, K_1, K_2, \dots), \quad (1.32)$$

under a RGT we will have  $\{\beta, K_1, K_2, \dots\} \rightarrow \{\beta', K'_1, K'_2, \dots\}$ . The  $\beta = \infty$  hyperplane is the so called critical surface (where  $\xi = \infty$ ). Starting from a critical point, a RGT produces another critical point. On the critical surface there is a FP with coordinates  $K_1^*, K_2^*, \dots$ . The FP defines a basin of attraction, i.e. a set of critical points that converge to it under RGT. The basin of attraction determines the universality class and all theories belonging to them show the same long-distance behavior. The flow along a relevant scaling field, whose end-point is the FP, is called renormalized trajectory (RT). In Yang-Mills theory, all the eigenoperators lying in the critical surface are irrelevant, and there is one marginal direction, which becomes relevant by higher order corrections, pointing out of this surface. The RT is the attractor of all flows terminating in the critical points that lie in the basin of attraction of the FP. Along the RT there are no scaling violations as, by construction, all irrelevant fields are zero. Thus, simulations done using an action along the exact RT will reproduce the continuum physics without discretization errors. Simulations on finite lattices of size  $L$  are done in a region of coupling space where  $\xi \ll L$ , that is they lie on flows that terminate at critical points that may be quite far from the FP. Corrections to scaling along these flows may therefore be large. A method to reduce these corrections is to adjust the action to lie on another flow that starts closer to the FP; since the flows are attracted by the RT, its location may be estimated by starting with the simple plaquette action and performing some blocking transformation.

A usual assumption is that the FP action is local, that is the strength of the couplings fall off exponentially with the size of the loops corresponding to the operators; nevertheless, it still involves an infinite number of couplings, but in practice one is forced to truncate the action to a finite number of interactions.

### 1.3.1 RG gauge improved actions in 2-parameter space

Investigations on the Renormalization Group in  $\sigma$ -models and Yang-Mills theories showed that a satisfactory treatment of RGT's can be achieved by restricting the action to a two-parameter space. The most popular examples are the Iwasaki and DBW2 actions where, in addition to the usual plaquette term, planar rectangular ( $1 \times 2$ ) loops are included

$$S = \beta \sum_x \left( c_0 \sum_{\mu < \nu} \left\{ 1 - \frac{1}{3} \text{Re} W_{\mu\nu}^{1 \times 1}(x) \right\} + c_1 \sum_{\mu, \nu} \left\{ 1 - \frac{1}{3} \text{Re} W_{\mu\nu}^{1 \times 2}(x) \right\} \right), \quad (1.33)$$

with the normalization condition  $c_0 = 1 - 8c_1$ . Note that eq. (1.33) has the same form as the tree-level Symanzik action eq. (1.13), eq. (1.14). The coefficients  $c_0, c_1$  are now determined by RG considerations.

Iwasaki [34] introduced a block-spin transformation with the purpose to obtain a gauge action that after a few blockings comes close to the RT. The strategy is the following: (i) one assumes to know the lattice action on the RT; (ii) the action can be expanded in perturbation theory; (iii) the correlation functions on the RT are calculated in perturbation theory. In principle, if one would know the (iii) then one can follow the opposite direction (iii)  $\rightarrow$  (i) and determine the action on the RT. In practice, one truncates eq. (1.32) to a two-parameter space and chooses as improved action a lattice action which is located near the RT. Iwasaki obtained for the coefficients in eq. (1.33) the numerical value  $c_1 = -0.331$ .

The QCD-TARO collaboration has investigated the flow of the Wilson action under blocking [35,36]. In particular, they used a blocking transformation with scale factor  $b = 2$  and determined the couplings on blocked lattices using the Schwinger-Dyson equation. The so called DBW2 action is obtained after a Double Blocking of the Wilson action in 2-dimensional coupling space; starting from the coupling ( $\beta = 6.3$ ) on a  $32^3 \times 64$  lattice, one obtains  $\beta_{1 \times 1} = \beta c_0 \sim 7.986, \beta_{1 \times 2} = \beta c_1 \sim -0.9169$ ; the corresponding coefficient in eq. (1.33) is then  $c_1 = -1.4088$ .

To summarize, in a two-parameter space, the coefficient  $c_1$  in eq. (1.33) takes different values for various choices of alternative actions

$$c_1 = \begin{cases} -1/12 & \text{Symanzik, tree level impr.} \\ -0.331 & \text{Iwasaki, RG} \\ -1.4088 & \text{DBW2, RG} \end{cases} \quad (1.34)$$

Notice that the strength of the rectangular loops for RG improved actions is larger than what is expected in order to cancel the  $O(a^2)$  at tree level, i.e. this method suggests an over-correction; this feature will be discussed later in chapter 3.

### 1.3.2 FP action

Hasenfratz and Niedermayer [33] used the framework of the renormalization group to propose a *classically perfect action*. The basic idea is to consider the FP described before, to evaluate the action at the FP, and then allow  $\beta$  to move away from  $\infty$ . This does not represent a RG flow but defines an action for every value of  $\beta$ . This defines a ‘‘classical perfect action’’, in the sense that its classical predictions agree

with those in the continuum, independently of whether the lattice is fine or coarse. One can say that the FP action is an on-shell tree-level Symanzik improved action to all orders in  $a$ . The detailed form of the FP action and the RT will depend on the form and parametrization of the block transformation; the theoretical properties of the FP action and RT are, however, independent of these details.

The next step is the observation that in asymptotically free theories like 4-dimensional  $SU(N)$ , the FP lies at  $\beta = \infty$  and in this limit the path integral describing the kernel of the blocking transformation can be calculated in the saddle point approximation. This leads to an equation in classical field theory which determines the FP action. However, this step is too demanding to be performed in a Monte Carlo simulation and one needs a sufficiently fast but at the same time accurate method to approximate the FP action. The first works on  $SU(3)$  gauge theory proposed a parametrization which used plaquettes, rectangular loops and their powers. Afterwards, [50] a new parametrization using plaquettes made by original and smeared (“fat”) links was investigated.

# Chapter 2

## The static quark potential

The potential between a static quark and anti-quark is an object of considerable theoretical interest that has been studied for almost 30 years. It defines the energy of gauge fields in the presence of two static color sources separated by a distance  $r$ . From the phenomenological point of view, in the limit where the mass of a quark  $q$  becomes large compared to typical QCD scale, bound states  $q\bar{q}$  are expected to be described by an effective nonrelativistic Schrödinger equation; the nonrelativistic potential is given by the static quark potential between charges at distance  $r$ . In the real world, this description is expected to be approximately valid for the  $b\bar{b}$  and maybe for the  $c\bar{c}$  spectra.<sup>1</sup> Due to asymptotic freedom of Yang-Mills theory, one expects at short distances a Coulomb-like behavior and the reliability of perturbation theory. At large distances quark confinement shows up and perturbative methods are no longer able to describe the behavior of physical observables; in this context, lattice gauge theories play an important rôle providing a full non perturbative approach. Lattice results can be used to investigate non-perturbative features of the static quark potential as well as to test the range of validity of perturbation theory, which is still an important phenomenological issue which has to be investigated more precisely.

In this chapter the static potential will be defined and the parameter-free predictions from perturbation theory and the bosonic string picture will be discussed. Then the lattice formulation, the simulation details and the continuum extrapolation will be explained and the results will be discussed and compared with perturbative and string predictions.

### 2.1 Definition

In the framework of the Euclidean functional integral, observables are gauge invariant functions of the field variables; as already mentioned, particular choices are the traces

---

<sup>1</sup> The fact that the interaction energy within a heavy quark bound state whose effective Hamiltonian contains a kinetic term will approach the static potential defined through the Wilson loop in the limit of infinite quark masses is still not clarified. Hence, in principle one should distinguish between static and heavy quark potential.

**Figure 2.1:** A Wilson loop  $\mathcal{C}_{r,t}$ .

of parallel transporters around closed loops, which are given on the lattice by

$$\text{Tr}_j U(\mathcal{C}), \quad (2.1)$$

where  $\text{Tr}_j$  denotes the trace in some representation  $j$  of the gauge group and  $U(\mathcal{C})$  indicates the product of link variables along the closed curve  $\mathcal{C}$ . The expectation values of these loop variables

$$W(\mathcal{C}) = \langle \text{Tr} U(\mathcal{C}) \rangle \quad (2.2)$$

are called Wilson loops; their special rôle is revealed by the fact that every observable which depends continuously on the link variables can be approximated arbitrarily well by expressions of the form

$$\sum_{n \geq 0} \sum_{\mathcal{C}_1, \dots, \mathcal{C}_n} c(\mathcal{C}_1, \dots, \mathcal{C}_n) \text{Tr} U(\mathcal{C}_1) \dots \text{Tr} U(\mathcal{C}_n). \quad (2.3)$$

As a special case consider a rectangular loop  $\mathcal{C}_{r,t}$  of side lengths  $r$  and  $t$  (Fig. 2.1); the static quark potential is related to the large  $t$  behavior of the corresponding Wilson loop in the fundamental representation<sup>2</sup>

$$V(r) \equiv - \lim_{t \rightarrow \infty} \frac{1}{t} \ln W(\mathcal{C}_{r,t}), \quad (2.4)$$

so that

$$W(\mathcal{C}_{r,t}) \sim_{t \rightarrow \infty} C e^{-tV(r)}. \quad (2.5)$$

The meaning of eq. (2.4) can be understood in the Hamiltonian formalism (see App. B), where states with several static external charges in different representations can be characterized by means of the corresponding behavior under gauge transformation. Let  $\Psi[U]$  be a wave function depending on the gauge links at time zero, and fix the temporal gauge

$$U(x, 0) = 1. \quad (2.6)$$

The transfer matrix  $\mathbb{T} = e^{-\mathbb{H}a}$  is a bounded hermitian operator which acts on these functions. The only gauge transformations left which respect this gauge are the time-independent ones; in this framework the gauge-invariant wave functions describe

<sup>2</sup>The same static quark potential could also be defined through the correlation of Polyakov loops, which are products of time-like links at a certain  $\vec{x}$  that wind around the lattice in the periodic time direction.

the physical states in the vacuum sector, while states with two color indices which transform under a gauge transformation eq. (1.3) according to

$$\Psi_{\alpha\beta}[U'] = V_{\alpha\gamma}(\vec{x})V_{\delta\beta}^{-1}(\vec{y})\Psi_{\gamma\delta}[U]. \quad (2.7)$$

describe a state with a static quark at  $\vec{x}$  and a static anti-quark at  $\vec{y}$ . In the following we consider  $\vec{y} = \vec{x} + \vec{r} = \vec{x} + r\hat{\mu}$ , with  $\mu = 1$ .

Due to the gauge invariance of the Hamiltonian, sectors with different distributions of external static charges decouple completely. The states eq. (2.7) form an Hilbert space  $\mathcal{H}_{\vec{x}\vec{y}}$ , and the static potential coincides with the ground state energy. The Wilson loop can be then interpreted as

$$W(\mathcal{C}_{r,t}) = \langle \Psi | e^{-t\mathbb{H}} | \Psi \rangle = \sum_n |\langle \Psi^{(n)} | \Psi \rangle|^2 e^{-tE_n} \sim_{t \rightarrow \infty} |\langle \Psi^{(0)} | \Psi \rangle|^2 e^{-tV(r)}, \quad (2.8)$$

where  $\Psi^{(n)}$  is a complete set of eigenstates of the Hamiltonian and  $\Psi$  is a state of type eq. (2.7)  $\in \mathcal{H}_{\vec{x}\vec{y}}$ .

In the continuum, the static quark potential can be described also through eq. (2.4); the Wilson loop is defined in the continuum gauge theory as

$$W(\mathcal{C}_{r,t}) = \left\langle \text{Tr} \mathcal{P} \exp \left( \oint_{\mathcal{C}_{r,t}} dx^\mu A_\mu \right) \right\rangle, \quad (2.9)$$

where  $\mathcal{P}$  denotes the path ordering along the loop  $\mathcal{C}_{r,t}$ , and the average is taken with respect to the Euclidean Yang-Mills action eq. (1.7).

## 2.2 The static quark potential in perturbation theory

At high energies, corresponding to small distances between the static quark-antiquark pair, asymptotic freedom justifies the application of perturbative methods. In this section we will consider the continuum Euclidean formulation of Yang-Mills theory.

In a perturbative analysis one can show [20, 21, 22] that at least up to two loop, after a convenient gauge fixing, all contributions in eq. (2.9) containing connections to the spatial components of the gauge fields  $A_i(\vec{r}, \pm t/2)$  vanish in the limit  $t \rightarrow \infty$ . The definition of the potential can then be reduced to

$$V_{\text{pert}}(r) = - \lim_{t \rightarrow \infty} \frac{1}{t} \log \left\langle \text{Tr} \mathcal{T} \exp \left( - \int d^4x J_\mu^a A_\mu^a \right) \right\rangle, \quad (2.10)$$

where  $r = |\vec{r}|$ ,  $\mathcal{T}$  is the time-ordering operator and

$$J_\mu^a = ig_0 \delta_{\mu 0} T_a [\delta(\vec{x}) - \delta(\vec{x} + \vec{r})] \theta(t^2/4 - x_0^2) \quad (2.11)$$

defines a static quark in  $\vec{x}$  and a static antiquark in  $(\vec{x} + \vec{r})$  that couple to the gauge field  $A_\mu$ .

From this definition, once a regularization scheme is fixed, for example dimensional regularization in  $d = 4 - \epsilon$  dimensions, one can perform the renormalization, subtracting the divergences by substituting the bare coupling with the renormalized one,  $\bar{g}$ . For example, at two loop one obtains [20, 21, 22]

$$V_{\text{pert}}(r) = \int \frac{d^3q}{(2\pi)^3} e^{i\vec{q}\vec{r}} \tilde{V}_{\text{pert}}(q) + V_{\text{self}}, \quad (2.12)$$

with  $q \equiv q_1 \equiv |\vec{q}|$ ,

$$\tilde{V}(q)_{\text{pert}} = -\frac{C_F 4\pi}{q^2} \alpha_{\overline{\text{MS}}}(\mu) \{1 + f_1(q, \mu) \alpha_{\overline{\text{MS}}}(\mu) + f_2(q, \mu) \alpha_{\overline{\text{MS}}}^2(\mu) + \dots\} \quad (2.13)$$

with  $C_F = \frac{4}{3}$  for SU(3),  $\alpha = \frac{\bar{g}^2}{4\pi}$ ; the coefficients  $f_1, f_2$  are known and will be discussed later. The constant part  $V_{\text{self}}$  corresponds to the self energy of the static sources; it has to be fixed by imposing an additional condition on the potential, for example that it vanishes at a given distance  $r$ .

From eq. (2.13) one can see that, once the self energy has been subtracted, the perturbative potential can be rewritten in a Coulomb-like form (the subscript is now omitted)

$$\tilde{V}(q) = -4\pi C_F \frac{\alpha_V(\mu)}{q^2}, \quad \mu^2 = q^2, \quad (2.14)$$

where  $\alpha_V(\mu)$  is a renormalized running coupling ("effective charge"), which defines the so called V-scheme, and is connected to  $\alpha_{\overline{\text{MS}}}(\mu)$  by the relation <sup>3</sup>

$$\alpha_V(q) = \alpha_{\overline{\text{MS}}}(\mu) (1 + f_1(q, \mu) \alpha_{\overline{\text{MS}}}(\mu) + f_2(q, \mu) \alpha_{\overline{\text{MS}}}^2(\mu) + \dots). \quad (2.15)$$

Alternatively, one can define a coupling from the potential in the coordinate space ( $\overline{V}$ -scheme)

$$V(r) = -C_F \frac{\alpha_{\overline{V}}(\mu)}{r}, \quad \mu = \frac{1}{r}, \quad (2.16)$$

or use the force (q $\bar{q}$ -scheme)

$$F(r) = \frac{dV}{dr} = C_F \frac{\alpha_{q\bar{q}}(\mu)}{r^2}, \quad \mu = \frac{1}{r}. \quad (2.17)$$

An important observation at this point is that only the coupling  $\alpha_{q\bar{q}}(\mu)$  defined through the force is also non-perturbatively defined, because the self energy term of the potential drops out. Non perturbatively it is not clear how to subtract the constant part, and hence  $\alpha_V$  and  $\alpha_{\overline{V}}$  are restricted to perturbation theory. This is a first reason to consider the force as natural observable for comparison between perturbation theory and non-perturbative QCD. Furthermore, although the couplings  $\alpha_V, \alpha_{\overline{V}}, \alpha_{q\bar{q}}$  differ only by kinematics (differentiation, the Fourier transformation), it makes a big difference for the applicability of perturbation theory which one is chosen to represent the potential. This problem will be discussed in details in sect.2.6.

<sup>3</sup>By matching perturbatively two schemes one always encounters a relative scale ambiguity: in this case for examples one has to specify the relation between  $q$  and  $\mu$ .

In general, if  $\bar{g}(\mu)$  is a renormalized coupling, its running is described by the  $\beta$ -function

$$\beta(\bar{g}) = \mu \frac{\partial}{\partial \mu} \bar{g}, \quad (2.18)$$

which has a perturbative expansion

$$\beta(\bar{g}) \sim_{\bar{g} \rightarrow 0} -\bar{g}^3 \{b_0 + b_1 \bar{g}^2 + b_2 \bar{g}^4 + \dots\}. \quad (2.19)$$

The first two coefficients are universal in the sense that they do not depend on the renormalization scheme in which  $\bar{g}$  is defined. For SU(3) gauge theory and  $N_f$  massless quarks one obtains [51], [52]

$$b_0 = \frac{1}{(4\pi)^2} \left( 11 - \frac{2}{3} N_f \right), \quad b_1 = \frac{1}{(4\pi)^4} \left( 102 - \frac{38}{3} N_f \right). \quad (2.20)$$

The three-loop coefficient of the  $\beta$ -function can be expressed as

$$b_2^S = b_2^S|_{N_f=0} + \frac{1}{(4\pi)^6} (e_1 N_f + e_2 N_f^2 + e_3 N_f^3) \quad (2.21)$$

with  $e_i$  listed in Table 2.1; some of them could be taken directly from the literature [53, 54, 20, 55, 56, 57], others such  $b_2^{\text{qf}}$  had to be computed by straightforward algebra. For comparison we included also the Schrödinger functional scheme <sup>4</sup>.

From eq. (2.18) follows that the behavior of  $\bar{g}$  at high energies is given by

$$\bar{g}^2 \sim_{\mu \rightarrow \infty} \frac{1}{b_0 t} - \frac{b_1 \log t}{b_0^3 t^2} + \mathcal{O}(t^{-3}(\log t)^2), \quad (2.22)$$

where

$$t = \log \left( \frac{\mu^2}{\Lambda_S^2} \right), \quad (2.23)$$

and  $\Lambda_S$  is an integration constant, the so-called  $\Lambda$ -parameter associated with the given scheme, with the dimension of a mass. Although classical non-Abelian gauge field theory does not contain any mass scale, the renormalization introduces this mass scale into the quantized theory: this fact is called *dimensional transmutation*. The solution of eq. (2.18),

$$\Lambda_S = \mu (b_0 \bar{g}^2)^{-b_1/2b_0^2} e^{-1/b_0 \bar{g}^2} \exp \left\{ - \int_0^{\bar{g}} dx \left[ \frac{1}{\beta(x)} + \frac{1}{b_0 x^3} - \frac{b_1}{b_0^2 x} \right] \right\}, \quad (2.24)$$

---

<sup>4</sup>In this discussion on different running couplings, we will include also a particular scheme used by the lattice community to solve the problem of matching low energy hadronic scales with high energy perturbative regimes. In the last ten years the ALPHA collaboration applied a finite size technique, the so called Schrödinger functional (SF) scheme, with the goal to compute the running coupling at short distances in units of the low energy scales of the theory [14, 16, 17]. The strategy is the following: one begins by formulating the theory in a finite spatial volume with linear extension  $L$  and periodic boundary conditions in all spatial directions. Next one introduces some renormalized coupling  $\bar{g}(L)^2$  which depends only on the scale  $L$  and which can hence be considered a running coupling. This coupling is then computed over a range of  $L$  through numerical simulations of the lattice theory, using a recursive procedure which allows one to go from large values of  $L$  (where one can make contact with the non-perturbative scales) to the perturbative domain where  $L$  is small. At this scale  $\alpha_{\text{SF}}(L)$  can be related analytically to other more commonly used schemes, like  $\overline{\text{MS}}$ , which are defined in infinite volume. The method has been applied successfully also to the case with two massless flavors [19].

$S$	$e_1$	$e_2$	$e_3$
$\overline{\text{MS}}$	$-\frac{5033}{18}$	$325/54$	$0$
V	$\frac{3}{2}\pi^4 - 24\pi^2 - \frac{2239}{6} - \frac{704}{3}\zeta(3)$	$\frac{377}{54} + \frac{104}{9}\zeta(3)$	$0$
$\overline{\text{V}}$	$-\frac{2239}{6} - \frac{704}{3}\zeta(3) + \frac{3}{2}\pi^4 - \frac{314}{3}\pi^2$	$\frac{377}{54} + \frac{104}{9}\zeta(3) + \frac{44}{9}\pi^2$	$-\frac{8}{81}\pi^2$
q $\overline{\text{q}}$	$\frac{3}{2}\pi^4 - \frac{314}{3}\pi^2 + \frac{3569}{6} - \frac{704}{3}\zeta(3)$	$\frac{2791}{54} + \frac{44}{9}\pi^2 + \frac{104}{9}\zeta(3)$	$\frac{32}{27} - \frac{8}{81}\pi^2$
SF	$-0.275(5) \times (4\pi)^3$	$0.0361(4) \times (4\pi)^3$	$-0.00175(1) \times (4\pi)^3$

**Table 2.1:** Coefficients  $e_i$  of eq. (2.21).

relates the coupling  $\bar{g} = \bar{g}(\mu)$  to the  $\Lambda$ -parameter and will be used to obtain a parameter free perturbative prediction for  $\bar{g}$ .

Eq. (2.15) can be generalized: given two running couplings  $\alpha_S$  and  $\alpha_{S'}$  defined in two different renormalization schemes, they can be matched in perturbation theory by

$$\alpha_{S'}(s\mu) = \alpha_S(\mu) + f_1^{S'S}(s)\alpha_S(\mu)^2 + f_2^{S'S}(s)\alpha_S(\mu)^3 + \dots, \quad (2.25)$$

where  $s$  is a relative scale which is a free parameter (for example  $s = q/\mu$  in eq. (2.15)).

The one-loop coefficient in eq. (2.25) assumes the general form

$$f_1^{S'S}(s) = \frac{1}{4\pi}(a_1 + a_2 N_f) - 8\pi b_0 \log(s), \quad (2.26)$$

where  $a_1$  and  $a_2$  are listed in Table 2.2, with  $\overline{\text{MS}}$  as reference scheme. The other coefficients can be evaluated by  $f_1^{S'S'}(s) = f_1^{SS''}(s) + f_1^{S''S'}(s)$ .

$S'$	$a_1$	$a_2$
V	$31/3$	$-10/9$
$\overline{\text{V}}$	$31/3 + 22\gamma_E$	$-10/9 - 4\gamma_E/3$
q $\overline{\text{q}}$	$-35/3 + 22\gamma_E$	$2/9 - 4\gamma_E/3$
SF	$-1.25563(4)/(4\pi)$	$-0.03983(2)/(4\pi)$

**Table 2.2:** Coefficients  $a_i$  of eq. (2.26) for  $S = \overline{\text{MS}}$

Using eq. (2.22) and the universality of  $b_0$  and  $b_1$ , one finds that the  $\Lambda$ -parameters in two schemes  $S$  and  $S'$  are related by

$$\Lambda_{S'} = \Lambda_S \exp \left\{ \frac{f_1^{S'S}(1)}{8\pi b_0} \right\} \quad (2.27)$$

exactly. The fact that this matching involves only one-loop coefficients is due to the fact that it is related to the asymptotic behavior at  $\mu \rightarrow \infty$ . For the 3-loop coefficient  $b_2^S$  of the  $\beta$ -function, we have

$$b_2^{S'} = b_2^S - b_1 \frac{f_1^{S'S}(s)}{4\pi} + \frac{b_0}{(4\pi)^2} \left( f_2^{S'S}(s) - f_1^{S'S}(s)^2 \right). \quad (2.28)$$

This relation, together with Table 2.1 and Table 2.2, can be used to obtain the two-loop coefficient in eq. (2.25)

$$f_2^{S'S}(s) = \frac{(4\pi)^2}{b_0} \left\{ b_2^{S'} - b_2^S + b_1 \frac{f_1^{S'S}(s)}{4\pi} - b_0 \left[ \frac{f_1^{S'S}(s)}{4\pi} \right]^2 \right\}. \quad (2.29)$$

As a particular example, one can consider the evaluation of the coefficient  $b_2^{\text{q}\bar{\text{q}}}$ ; the starting point is the relation

$$\alpha_{\text{q}\bar{\text{q}}}(\mu) = \alpha_{\bar{V}}(\mu) \left( 1 + 2 \frac{\beta_{\bar{V}}(\bar{g}(\mu))}{\sqrt{4\pi\alpha_{\bar{V}}(\mu)}} \right), \quad (2.30)$$

which follows directly from the definition of the force.

Eq. (2.30) defines the connection between the  $\text{q}\bar{\text{q}}$  and  $\bar{V}$  schemes; in particular, one can read off the matching coefficients

$$f_1 = -2b_0 4\pi, \quad f_2 = -2b_1 (4\pi)^2, \quad (2.31)$$

which are related to the case  $s = 1$  in eq. (2.25)<sup>5</sup>, with  $S = \bar{V}$  and  $S' = \text{q}\bar{\text{q}}$ . From eq. (2.28) one can easily obtain

$$b_2^{\text{q}\bar{\text{q}}} = b_2^{\bar{V}} - b_0^3, \quad (2.32)$$

which is the simplest way to obtain  $b_2^{\text{q}\bar{\text{q}}}$  from  $b_2^{\bar{V}}$ , which is known from the literature.

In the perturbative matching of different schemes the choice of the relative scale factor  $s$  plays an important rôle for the quality of the perturbative prediction [53, 58]. The only viable criterion for fixing  $s$  appears to be to demand that the coefficients  $f_i(s)$  are small ("fastest apparent convergence"). For instance, the choice

$$s = s_0 = \frac{\Lambda_{S'}}{\Lambda_S} \quad (2.33)$$

yields

$$f_1(s_0) = 0, \quad (2.34)$$

$$f_2(s_0) = \frac{(4\pi)^2}{b_0} \left[ b_2^{S'} - b_2^S \right], \quad (2.35)$$

<sup>5</sup>Note that the values of  $b_2$  computed via eq. (2.28) must be independent on the factor  $s$ , so that one is allowed to consider a particular case.

and  $f_2(s_0)$  can be shown to be close to the minimum of  $|f_2(s)|$ .

This relative scale ambiguity is related to the fact that we are matching two couplings at finite  $\mu$ ; alternatively, if one knows the  $\Lambda$  parameter in a given renormalization scheme, then truncating in eq. (2.19) after the term  $b_{n-1}$  and solving eq. (2.24) (numerically) for  $\bar{g}$  at given  $\mu$  (in units of  $\Lambda$ ) defines the  $n$ -loop RG solution for the coupling. In single scale problems, such as the static potential depending only on the separation  $r$ , this is expected to be the best perturbative prediction. In contrast to the expansion eq. (2.25), the matching is now realized at  $\mu = \infty$  and one does not need to fix a relative scale parameter  $s$ .

The ALPHA collaboration evaluated  $\Lambda_{\overline{\text{MS}}}$  for  $N_f = 0$  from lattice calculations employing the Schrödinger functional scheme [15], extracting it at a sufficiently high scale  $\mu$  where the perturbative error is negligible and converting it to the  $\overline{\text{MS}}$  scheme. In terms of the length scale  $r_0 \approx 0.5\text{fm}$ , which will be defined in section 2.4.1, the result is

$$\Lambda_{\overline{\text{MS}}}r_0 = 0.602(48), \quad (2.36)$$

corresponding to

$$\Lambda_{\overline{\text{MS}}} \approx 238 \text{ MeV}. \quad (2.37)$$

This result, together with the ratios  $\Lambda_S/\Lambda_{\overline{\text{MS}}}$  and the 3-loop coefficient of the  $\beta$ -function  $b_2^S$ , allows to use eq. (2.24) for a parameter-free perturbative prediction for  $\alpha_S$  from 2- and 3-loop RG. For completeness the numerical values of  $\Lambda_S/\Lambda_{\overline{\text{MS}}}$  and  $b_2^S$  for  $N_f = 0$  are collected in Table 2.3,

scheme $S$ :	$q\bar{q}$	$V$	$\bar{V}$	SF
$\Lambda_S/\Lambda_{\overline{\text{MS}}}$	$\exp(\gamma_E - 35/66)$	$\exp(31/66)$	$\exp(31/66 + \gamma_E)$	0.48811(1)
$b_2^S \times (4\pi)^3$	1.6524	2.1287	4.3353	0.483(9)

**Table 2.3:** Ratio of  $\Lambda$ -parameters and 2-loop coefficient of the  $\beta$ -function for various schemes for  $N_f = 0$ . These results follow from [53, 54, 20, 55, 56, 59, 57, 60].

The couplings  $\alpha_{q\bar{q}}$  and  $\alpha_{\bar{V}}$  from 2- and 3-loop RG are illustrated in Fig. 2.2, using the central value  $\Lambda_{\overline{\text{MS}}}r_0 = 0.602$  (the 8% overall uncertainty of this number corresponds to a common small horizontal shift of all curves in the figure). By analyzing the relative difference between the 2- and 3-loop behavior of  $\alpha_{q\bar{q}}$ , one observes that the perturbative expansion appears quite well behaved up to distances  $r \sim 0.25\text{fm}$ . At  $r \sim 0.2\text{fm}$  one would expect the 3-loop curve to have an accuracy of about 10%. Since the force is completely equivalent to  $\alpha_{q\bar{q}}$  it is given with the same relative accuracy; the potential may be obtained by integration of the force. On the other hand, we note that the 3-loop coefficients  $b_2$  for  $V$  and  $\bar{V}$ -schemes are larger in comparison to  $b_2^{q\bar{q}}$  (see Table 2.3), in particular in the  $\bar{V}$  scheme. As a consequence, the difference between the 2-loop and the 3-loop running coupling in this scheme is only small at very short distances and this perturbative expansion appears to be applicable only up to  $\alpha \sim 0.15$ . This is also illustrated in Fig. 2.2.

Furthermore, if one observes the numerical values of the matching coefficients  $f_2(s_0)$  eq. (2.25) for  $N_f = 0$  in Table 2.4, one can notice that the SF-scheme is very

**Figure 2.2:** Running coupling obtained by integration of the RG with truncation of the  $\beta$ -functions at 2- and 3-loop. We use  $\Lambda_{\overline{\text{MS}}} = 238\text{MeV}$  [15]

close to the  $\overline{\text{MS}}$ -scheme, the  $q\bar{q}$  scheme is not very far, but the other schemes have quite large values of  $f_2(s_0)$  in relation to the  $\overline{\text{MS}}$ -scheme. In particular, the large coefficient between the  $\overline{\text{MS}}$  scheme and the  $\overline{V}$  scheme means that the direct expansion of the coordinate space potential in terms of  $\alpha_{\overline{\text{MS}}}$  (or  $\alpha_{\text{SF}}$ ) is badly behaved, as it has been pointed out in [53, 61].

$f_2^{S'S}(s_0)$	$\overline{\text{MS}}$	$q\bar{q}$	$V$	$\overline{V}$
$q\bar{q}$	1.0653			
$V$	1.6095	0.5441		
$\overline{V}$	4.1303	3.0650	2.5208	
SF	-0.271(10)	-1.336(10)	-1.880(10)	-4.401(10)

**Table 2.4:** 2-loop coefficients for  $s = s_0 = \Lambda_{S'}/\Lambda_S$  and  $N_f = 0$ .

For the Schrödinger functional coupling,  $\alpha_{\text{SF}}(\mu)$ , it was observed in [15] that it is in remarkable qualitative agreement with perturbation theory for  $\alpha < 0.3$  and for  $\alpha < 0.2$  the 3-loop expression describes  $\alpha_{\text{SF}}(\mu)$  within better than 2%. It is an interesting question, whether the coupling in this scheme is a special case or whether this is a more “general property of the theory”. For this purpose the perturbative prediction for the potential and the force will be compared with our non-perturbative computation in section 2.6.

## 2.3 Quark confinement and the bosonic string picture

Perturbation theory can be applied to gauge theories in the continuum as well as on the lattice. Several interesting aspects, however, are inaccessible to a perturbative treatment and require non-perturbative methods. One of these is the strong coupling expansion, which amounts to expanding in powers of the inverse coupling and can be used in the lattice formulation to investigate the region where  $g_0$  is large. If one applies this method to the Wilson loops eq. (2.5) [62] one finds that the leading term is

$$W(\mathcal{C}_{r,t}) = 2e^{-\sigma r t} + \dots, \quad (2.38)$$

where  $\sigma = -\log \frac{1}{24g_0^2}$  is the so-called string tension. By analyzing higher orders in the expansion it was shown [63] that the strong coupling expansion of  $W(\mathcal{C}_{r,t})$  has a finite range of convergence and within this range the Wilson loop obeys eq. (2.38), which is called the *area law* and establishes that the potential  $V(r)$  asymptotically rises linearly with  $r$

$$V(r) \sim_{r \rightarrow \infty} \sigma r. \quad (2.39)$$

This behavior is called linear quark confinement [11].

The strong coupling expansion has given an important contribution to an intuitive picture of the confinement mechanism, where a tube of non-Abelian chromoelectric flux holds quarks and antiquarks together. In the limit of very large  $r$ , one can expect that these flux tubes behave like strings with fixed ends, and the expectation values of large Wilson loops could be predicted by an effective bosonic string theory [26]. In this theory, the Wilson loops are expressed in terms of functional integrals over all two-dimensional surfaces bounded by the loops. For  $r, t$  large, the configuration with the minimal area will dominate; the deviation of the fluctuating surface from the minimal one is described by a bosonic vector field, whose action defines the effective string theory. Under this assumption, the static quark potential  $V(r)$  has the asymptotic expansion for large  $r$  [27, 28] <sup>6</sup>

$$V(r) = \sigma r + \mu + \frac{\gamma}{r} + \mathcal{O}\left(\frac{1}{r^2}\right), \quad (2.40)$$

where  $\mu$  is a mass constant depending on the regularization and

$$\gamma = -\frac{\pi}{24}(d-2) \quad (2.41)$$

is a quantum effect that is characteristic of the relativistic bosonic string.  $\gamma$  is universal in the sense that it depends only on the dimension  $d$  of the space-time and is common to a large class of effective string actions. The lattice evaluation of the static quark potential  $V(r)$  should allow in principle a test of the validity of eq. (2.40). However, it turns out that the statistical and systematic errors increase rapidly at

<sup>6</sup>We assume as leading order of the effective string theory  $V(r) = \sigma r + \text{const.}$  Eq. (2.40) hence represents the next-to-leading order expression.

large  $r$ , and thus it is very difficult to obtain reliable values for  $V(r)$  at large distances. Lüscher and Weisz proposed a new type of simulation algorithm [64] for the  $SU(N)$  gauge theory that leads to an exponential reduction of the statistical errors in numerical calculations of Polyakov loop correlation functions. They evaluated the force  $V'(r)$  and the second derivative  $V''(r)$  up to  $r \approx 1\text{fm}$  [29] with sufficient precision to test the string predictions. For  $d = 3$  their numerical results at large  $r$  are in full agreement with eq. (2.40) without need of further corrections. For  $d = 4$ , if one allows for a higher order term

$$V(r) = \sigma r + \mu - \frac{\pi}{24r}(d-2) \left(1 + \frac{b}{r}\right) \quad (2.42)$$

one finds agreement in the range  $r > 0.5\text{fm}$  by setting  $b = 0.04\text{fm}$ .

As pointed out by the authors, this good agreement seems surprising, because at such distances one can strongly doubt the physical picture of a thin fluctuating flux tube.

A further important test is related to the energy spectrum of the excited string levels, which at next to leading order of the effective string theory are given by [65, 66, 67]

$$E_n = \sigma r + \mu + \frac{\pi}{r} \left[ -\frac{1}{24}(d-2) + n \right]. \quad (2.43)$$

In particular, to this order the energy gap  $\Delta E = E_1 - V(r)$  is equal to  $\frac{\pi}{r}$ . It was observed that the spectrum  $E_n$  does not seem to agree with the one obtained in the effective string picture [68, 69, 70, 71, 72], although this argument alone can not exclude the validity of the effective theory, since higher order corrections could be responsible for the large discrepancy. Moreover, one has to take into account the technical difficulties in the evaluation of the spectrum. More investigations are then needed to understand if the string picture is really able to describe the large distance properties including static quark confinement and the excited states.

## 2.4 Evaluation of the potential on the lattice

Since the original work by Creutz in the  $SU(2)$  gauge theory, many computations of the potential from lattice gauge theories have been performed in  $SU(3)$ , but the short distance regime has not yet been investigated convincingly. The reason is that by "the potential" one means the potential in infinite volume; in practice one considers systems with finite extension  $L$  and one knows that for the force at distances up to  $r \sim 0.5\text{fm}$ , the deviation from infinite volume are small on an  $L^4$  torus with  $L = 1.5\text{fm}$ . With such a physical value of  $L$ , an investigation of distances of  $r \sim 0.05\text{fm}$  with control over  $O(a/r)$  effects requires very large lattices. Setting the number of flavors  $N_f = 0$  (for our purposes this means the pure Yang-Mills theory), large lattices may nowadays be simulated. We studied the static potential in the range  $0.05\text{ fm} \leq r \leq 0.8\text{ fm}$ , employing a sequence of lattices up to  $64^4$ . This study of the potential from short to intermediate distances was performed using the standard Wilson action and extrapolating the results to the continuum. In chapter 3 we will consider the potential for improved actions with the purpose to investigating the

lattice artifacts, and we will restrict ourselves to coarser lattices leaving out the goal to perform a continuum extrapolation.

### 2.4.1 Setting the scale in Yang-Mills lattice theories

The first step in the evaluation of renormalized quantities from lattice QCD is to set the scale. In a pure gauge theory the coupling  $g_0$  is the only parameter in the Lagrangian, then one has to specify one physical quantity in order to renormalize the theory. It turns out that it is convenient to choose a dimensionful long distance observable, which introduces *the* scale into the theory: predictions of all other dimensionful quantities are then expressed in units of this scale. They are well defined renormalized quantities and can be extrapolated to the continuum limit from results at finite resolution.

It is clear that the scale should be chosen with care since it influences the precision of many predictions. From the confinement picture, one expects a linearly growing potential at large distances, with a certain slope which defines the string tension. One possible choice to set the scale is then

$$\sigma = \lim_{r \rightarrow \infty} F(r), \quad (2.44)$$

where  $F(r) = \frac{dV}{dr}$ . This limiting procedure is not easy to perform because statistical and systematic errors in the force increase with the distance. Moreover, if one believes the string picture described in sec. 2.3, one can expect that higher order terms proportional to  $b$  in eq. (2.42) can be neglected only at very large distances and this should be taken into account in the extraction of the string tension from the potential.

In most cases, the string tension is extracted from lattice data by fitting the potential with a three-parameter formula

$$V(r) = a_1 + a_2 r + \frac{a_3}{r}, \quad (2.45)$$

but to identify  $a_2$  with the string tension can be a source of large and uncontrolled systematic errors.

For this reason it is desirable to use the force at intermediate distances to determine the scale. One can observe that both  $b\bar{b}$  and  $c\bar{c}$  spectra can be accurately described by one effective potential in the range of  $r \approx 0.2$  fm to  $r \approx 1$  fm, and this suggests that the range where one has the best information on the force  $F(r)$  between static quarks is at distances of around 0.5 fm. One then calculates  $r(c)$  satisfying the equation [25]

$$r^2 F(r) \Big|_{r=r(c)} = c, \quad r_0 = r(1.65) \approx 0.5 \text{ fm}. \quad (2.46)$$

When one is interested in short distance properties of the theory, it is convenient to choose a smaller reference length scale, because large distances on fine lattices are very expensive from the computational point of view. We decided to separately consider two regions,  $0.05 \text{ fm} \leq r \leq 0.3 \text{ fm}$  and  $0.2 \text{ fm} \leq r \leq 0.8 \text{ fm}$ , where the first requires very large lattices and small lattice spacings and the second one had been

simulated before on coarser lattices [73]. The region of overlap serves for calibration. We therefore introduced an additional scale

$$r_c = r(0.65) \quad (2.47)$$

and evaluated its relation to  $r_0$ .

### 2.4.2 Definition of the force

In the continuum, the definition eq. (2.46) is unique, but at finite lattice spacing one has to specify which discretization of the force is to be used. Given the potential  $V(r)$  in a certain direction, in general one has

$$F(r') = [V(r) - V(r - a)] / a. \quad (2.48)$$

The naive choice for  $r'$  would be

$$r' = r_n \equiv r - \frac{a}{2}. \quad (2.49)$$

Instead of  $r_n$ , we decided to use a distance  $r_I$  chosen such that the force on the lattice has no deviations from the force in the continuum when evaluated at tree level. On the lattice, the force at tree level is given by

$$F_{tree}(r) = -\frac{4}{3} \frac{g_0^2}{a} \int_{-\pi}^{\pi} \frac{d^3 k}{(2\pi)^3} \frac{\cos(rk_1/a) - \cos((r-a)k_1/a)}{4 \sum_{j=1}^3 \sin^2(k_j/2)} \quad (2.50)$$

and one would introduce  $r_I$  such that

$$F(r_I) = \frac{4}{3} \frac{g_0^2}{4\pi r_I^2} + O(g_0^4). \quad (2.51)$$

The lattice artifacts remain only in the  $O(g_0^4)$  terms;  $F(r_I)$  is called a *tree-level improved observable*.

In the SU(2) theory it has been observed that by adopting this definition the remaining lattice artifacts in the force are surprisingly small [25] and here we shall again find no evidence for them as long as  $r > 2a$ .

Explicitly we have from eq. (2.50)

$$(4\pi r_I^2)^{-1} = -[G(r, 0, 0) - G(r - a, 0, 0)] / a, \quad (2.52)$$

where

$$G(\vec{r}) = \frac{1}{a} \int_{-\pi}^{\pi} \frac{d^3 k}{(2\pi)^3} \frac{\prod_{j=1}^3 \cos(x_j k_j / a)}{4 \sum_{j=1}^3 \sin^2(k_j / 2)} \quad (2.53)$$

is the (scalar) lattice propagator in 3 dimensions, for general  $\vec{r} = (x_1, x_2, x_3)$ . In [74] a method was proposed to construct it directly in coordinate space using a recursive relation. We extended the method to 3-d finding the necessary invariant of the recursion relation eq. (C.8). Formulae are listed in App. C.

### 2.4.3 Computation of the potential and force

The evaluation of the potential from eq. (2.8) is technically difficult because of the presence of higher order excitations, so that the ground state becomes dominant only at large values of  $t$ , where the statistical uncertainties can be very large. In order to enhance the overlap with the physical ground state one can use smearing techniques, which consists of building operators which describe in our case static quarks and antiquarks in an “optimized” way.

In particular, we adopted a smearing operator  $\mathcal{S}$  which acts on the spatial components of the gauge fields via [75]

$$\begin{aligned} \mathcal{S}U(x, k) = \mathcal{P}_{\text{SU}(3)} \left\{ U(x, k) + \alpha \sum_{j \neq k} [U(x, j)U(x + a\hat{j}, k)U^\dagger(x + a\hat{k}, j) \right. \\ \left. + U^\dagger(x - a\hat{j}, j)U(x - a\hat{j}, k)U(x + a\hat{k} - a\hat{j}, j)] \right\}, \end{aligned} \quad (2.54)$$

where  $\mathcal{P}_{\text{SU}(3)}$  denotes the projection into the group SU(3) and  $\alpha$  is an adjustable parameter.<sup>7</sup>

For different smearing levels  $l = 0, \dots, M - 1$  one then constructs smeared spatial links according to

$$U_l(x, k) = \mathcal{S}^l U(x, k). \quad (2.55)$$

In particular we chose

$$\alpha = \frac{1}{2}, \quad M = 3. \quad (2.56)$$

In [73]  $n_l$  was set to

$$n_l \sim \frac{l}{2} \left( \frac{r_0}{a} \right). \quad (2.57)$$

According to this choice,  $n_2$  corresponds to what was estimated to be the optimal smearing in [76]. Since we want to compute the potential for shorter distances, where one can reach high precision, we adopted in general smaller values than these.

Another difficulty is the fact that the Wilson loops eq. (2.8) decay exponentially for large  $t$ . In order to measure these values in a Monte Carlo simulation with statistical significance, also the variance of the matrix should decrease exponentially with  $t$ . To achieve this, one can apply a so-called multi-hit procedure [77] to the time-like links, which are substituted by their expectation values in the fixed configuration of the other field variables

$$\bar{U}(x, 0) = \frac{\int dU(x, 0)U(x, 0)e^{-S[U(x, 0)]}}{\int dU(x, 0)e^{-S[U(x, 0)]}}, \quad (2.58)$$

where  $S[U(x, 0)]$  denotes the part of the action depending on  $U(x, 0)$ . For a general observable, the substitution of  $U(x, 0)$  with  $\bar{U}(x, 0)$  is allowed under the following

<sup>7</sup>For any  $3 \times 3$  matrix  $V$ ,  $\mathcal{P}_{\text{SU}(3)}V$  denotes the matrix  $W \in \text{SU}(3)$  which maximizes  $\text{Re Tr}(WV^\dagger)$

restrictions: (i) the observable must depend linearly on the considered links and (ii) no pair of substituted links may be coupled through the action.

For SU(2), an exact expression for eq. (2.58) can be obtained in terms of modified Bessel functions. For SU(3), there is no analytic expression and eq. (2.58) is evaluated numerically by means of Monte Carlo integration.<sup>8</sup> At fixed  $r$ , one then forms a  $M \times M$  correlation matrix of Wilson loops

$$C_{lm}(t) = \left\langle \text{Tr} \left\{ V_l(0, r\hat{1}) \bar{V}(r\hat{1}, r\hat{1} + t\hat{0}) V_m^\dagger(t\hat{0}, r\hat{1} + t\hat{0}) \bar{V}^\dagger(0, t\hat{0}) \right\} \right\rangle \quad (2.59)$$

$$= C_{ml}(t),$$

where

$$V_l(x, x + r\hat{1}) = U_l(x, 1) U_l(x + a\hat{1}, 1) \dots U_l(x + (r - a)\hat{1}, 1), \quad (2.60)$$

$$\bar{V}(x, x + t\hat{0}) = \bar{U}(x, 0) \bar{U}(x + a\hat{0}, 0) \dots \bar{U}(x + (t - a)\hat{0}, 0). \quad (2.61)$$

The correlation matrices were computed on field configurations generated by a hybrid algorithm with a mixture of  $N_{\text{or}}$  over-relaxation steps per heat bath step [78, 79]. The ratio  $N_{\text{or}}$  increases with the coupling  $\beta$ , and in practice we adopted

$$N_{\text{or}} \approx 1.5(r_0/a). \quad (2.62)$$

In a Monte Carlo simulation the configurations are correlated, hence the measurements are not statistically independent. We decided to perform a measurement of Wilson loops every  $N_{it/meas}$  sweeps, where  $N_{it/meas}$  is chosen such that the time needed for the updating is about half of the time used for the measurement.

By collecting the data in bins and applying the so-called *jackknife* procedure, it is possible to check that with this criterion the measurements are practically uncorrelated.

The simulation parameters for  $5.7 \leq \beta \leq 6.4$  are reported in [73], while for the new simulations in the range  $6.57 \leq \beta \leq 6.92$  they are listed in Table 2.5. We used  $L \times L \times L \times T$  lattices, with  $T = L$ . The parameters  $\beta$  and  $L/a$  have been chosen such that

$$L/r_0 \sim 3.3. \quad (2.63)$$

This condition is necessary because the physical results are obtained in the limit  $L \rightarrow \infty$ , and by using a finite volume one has to be sure that finite-size effects are negligible. In [73] it was shown that eq. (2.63) is safe and no finite volume effect is observed.

We evaluated the Wilson loops in eq. (2.59) for each value of the loop size  $r, t$ , with  $a \leq r \leq r_{\text{max}}$  and  $a \leq t \leq t_{\text{max}}$ . Due to the high precision that one can reach at short distances, only 40 to 75 measurements were sufficient to extract the observables, and with relatively modest computational effort we could extend the calculations to  $a \sim 0.025$  fm where a  $64^4$  lattice had to be simulated.

<sup>8</sup>We evaluated the average using 15 Cabibbo-Marinari iterations.

**Table 2.5:** Simulation parameters.

$L/a$	$\beta$	$n_0$	$n_1$	$n_2$	$N_{\text{or}}$	$r_{\text{max}}/a$	$t_{\text{max}}/a$
40	6.57	0	77	153	18	7	11
48	6.69	0	53	106	22	10	12
56	6.81	0	72	144	25	12	14
64	6.92	0	94	188	29	12	16

### 2.4.4 Analysis details

The correlation matrices eq. (2.59) were analyzed using a variational method, which was proposed in [80, 81]. For any  $r$  and  $t_0$  fixed ( $t_0 = 0$  in practice), one solves a generalized eigenvalue problem

$$C_{lm}(t)v_{\alpha,m}(t, t_0) = \lambda_{\alpha}(t, t_0)C_{lm}(t_0)v_{\alpha,m}(t, t_0), \quad \lambda_{\alpha} > \lambda_{\alpha+1}, \quad (2.64)$$

which corresponds to finding the eigenvalues of the symmetric matrix  $\bar{C} = C(t_0)^{-1/2}C(t)C(t_0)^{-1/2}$ . For the Wilson action, the positivity of the transfer matrix ensures that  $C(t)$  is positive definite for all  $t$  (see appendix B).<sup>9</sup> One can prove that the energies  $E_{\alpha}$  are related to the generalized eigenvalues by the relation

$$aE_{\alpha} = \ln(\lambda_{\alpha}(t - a, t_0)/\lambda_{\alpha}(t, t_0)) + O(e^{-t\Delta E_{\alpha}}), \quad (2.65)$$

where  $\Delta E_{\alpha} = \min_{\beta \neq \alpha} |E_{\alpha} - E_{\beta}|$ . The static quark potential corresponds to the ground state energy,  $V(r) \equiv E_0$ .

By using this method one expects that the coefficients of the higher order terms in eq. (2.65) are suppressed and one can read off the energy values already at moderately large  $t$ . Solving the generalized eigenvalue problem eq. (2.64) is indeed equivalent to looking for a linear combination of operators appearing in the correlation function such that the state with the lowest energy has the maximal weight.

We decided to extract the potential  $V(r)$  projecting the Wilson loop correlation function

$$W(t) = v_0^T C(t)v_0, \quad (2.66)$$

where  $v_0$  is the ground state eigenvector computed for  $t = t_0 + a$  in eq. (2.64) corresponding to the ground state, and then constructing the effective potential

$$aV(r) = -\ln \left( \frac{W(t)}{W(t-a)} \right). \quad (2.67)$$

Beside the potential, one is also interested in the energy gap between the ground state and the first excited state

$$\Delta E_0 = E_1 - E_0, \quad (2.68)$$

<sup>9</sup>For gauge actions of kind eq. (1.33) containing not only the plaquette, but also other operators, this property is not satisfied, and the implications for the applicability of the variational method are discussed in chapter. 3.

**Figure 2.3:** The potential evaluated at  $r \sim r_0/2$  for different couplings as a function of  $\exp(-t_{\min}\Delta)$ ;  $t_{\min}$  will be determined such that  $\exp(-t_{\min}\Delta) < 0.3$ . Similar results hold for other values of  $r$ .

which dominates the finite time corrections in the extraction of  $V(r)$ . We estimated them by

$$a\Delta E_0 = \ln(\lambda_1(t-a, t_0)/\lambda_1(t, t_0)) - \ln(\lambda_0(t-a, t_0)/\lambda_0(t, t_0)). \quad (2.69)$$

To demonstrate that these corrections are small, we computed  $aV(r)$  from eq. (2.67) for  $r \approx r_0/2$  and  $r \approx r_0/4$  and we plotted it as a function of  $\exp(-t\Delta E_0)$ ; as in [73] we found that for  $t > t_{\min}$  excited states contaminations are very small when  $\exp(-t_{\min}\Delta E_0) < 0.3$  (Fig. 2.3), and we used this criterion to establish at which  $t$  the systematic errors in eq. (2.67) are negligible with respect to the statistical uncertainties. In [73] a continuum extrapolation of the quantity  $r_0\Delta E_0$  was performed, yielding

$$r_0\Delta E_0|_{r=r_0} = 3.3(1). \quad (2.70)$$

Since the gap grows towards small  $r$  from  $\approx 3/r_0$  at  $r = r_0$  to  $\approx 7/r_0$  at  $r = 0.1r_0$ , the short distance region is easiest in this respect.

All errors were computed by jackknife binning, and the results for the potential and force are listed in appendix A, in particular in tables A.4, A.2.

### 2.4.5 Interpolation

Solving eq. (2.46) and evaluating the force and potential at distances  $r = xr_c$  for given  $x$ , requires the interpolation of those quantities. While this can in principle be done in many ways, it is advantageous to use physics motivated interpolation formulae.

**Figure 2.4:** The ratio  $r_c/r_0$  for  $5.95 \leq \beta \leq 6.57$  (circles) including the continuum extrapolation (solid point). The data for  $5.95 \leq \beta < 6.57$  are taken from [73].

For the force we followed [25] choosing the interpolation function

$$F(r) = f_1 + f_2 r^{-2}, \quad (2.71)$$

between two neighboring points. The systematic error arising from the interpolation was estimated by adding a term  $f_3 r^{-4}$  and taking a third point. The difference between the two interpolations was added (linearly) to the statistical uncertainty. We observed that at least for  $r \gtrsim 0.4r_0$  the interpolation error is smaller than the statistical uncertainty. For small distances the systematic error increases and can be of the order of the statistical one or even bigger.

The potential is interpolated by the corresponding ansatz

$$V_I(r) = v_1 + v_2 r + v_3 r^{-1}. \quad (2.72)$$

Here two points are chosen such that the desired value of  $r$  is in between. For the choice of a neighboring third point one has two possibilities, leading to two results. Their difference was taken as the interpolation error. Also in this case the systematic errors are larger than the statistical ones at short distances while at large distances the situation is reversed.

It is important to stress that the interpolation formulas eq. (2.71), eq. (2.72) provide excellent approximations of the  $r$  dependence only locally, and to use instead a global fit in a large range could be a source of large systematic errors.

#### 2.4.6 The ratio $r_c/r_0$ and parametrization of $r_0/a$

Following the procedure described in the previous sections, we evaluated  $r_c/a$  and  $r_0/a$  in the region  $5.95 \leq \beta \leq 6.57$  where both quantities are accessible. Figure 2.4 shows the ratio  $r_c/r_0$  for several lattice spacings as a function of  $(a/r_0)^2$ . No dependence on the resolution is seen within the errors of below 1%. A continuum extrapolation gives

$$r_c/r_0 = 0.5133(24) \quad (2.73)$$

**Table 2.6:** Results for  $r_0/a$  [73] and  $r_c/a$ . For comparison also the values from the interpolation formula eq. (2.79) are shown.

$\beta$	$r_0/a$	eq. (2.79)	$\beta$	$r_c/a$	eq. (2.79),eq. (2.73)
5.7	2.922(9)	2.938	6.57	6.25(4)	6.22
5.8	3.673(5)	3.665	6.69	7.29(5)	7.25
5.95	4.898(12)	4.912	6.81	8.49(5)	8.48
6.07	6.033(17)	6.038	6.92	9.82(6)	9.86
6.2	7.380(26)	7.383			
6.4	9.74(5)	9.741			

and we note that it is safe to use eq. (2.73) also at finite lattice spacings starting around  $\beta = 6.4$ .

The direct determination of  $r_0/a$  for  $5.7 \leq \beta \leq 6.4$  [73]<sup>10</sup> and the new computations of  $r_c/a$  in the range  $6.57 \leq \beta \leq 6.92$  may be combined with  $r_c/r_0=0.5133(24)$  to obtain  $r_0/a$  in the whole range  $5.7 \leq \beta \leq 6.92$ . The results are reported in Table 2.6. Once  $r_0/a$  is known for several  $\beta$  values, it is useful to attempt a phenomenological representation in terms of an interpolating formula giving  $r_0/a$  in the whole range of couplings. One can start from the renormalization group equation for the bare coupling; on the lattice the  $\beta$  function associated to  $g_0$  is defined as,

$$\beta(g_0) = -a \frac{\partial g_0}{\partial a} = -b_0 g_0^3 - b_1 g_0^5 + \dots \quad (2.74)$$

Solving eq. (2.74) yields the  $\Lambda$ -parameter associated to the lattice

$$\Lambda_{LAT} = \lim_{g_0 \rightarrow 0} \frac{1}{a} e^{-1/(2b_0 g_0^2)} (b_0 g_0^2)^{-b_1/(2b_0^2)}. \quad (2.75)$$

In pure gauge theory every physical quantity with dimensions of a mass must be proportional to  $\Lambda_{LAT}$  in the continuum limit; therefore the mass (or  $a/r_0$  in our case) in lattice units, which is the quantity that one evaluates in numerical simulations, varies as a function of  $g_0$  according to

$$\frac{a}{r_0} = A e^{-1/(2b_0 g_0^2)} (b_0 g_0^2)^{-b_1/(2b_0^2)} e^{-c_1 g_0^2 - c_2 g_0^4 - \dots}, \quad (2.76)$$

where  $A$  is a constant and the terms with  $c_1, c_2, \dots$  are due to higher order contributions to the  $\beta$  function. This behavior is also called *asymptotic scaling*.

The leading behavior is then given by

$$\frac{a}{r_0} \propto e^{-\beta/(12b_0)}, \quad \beta = 6/g_0^2, \quad (2.77)$$

<sup>10</sup>In [73] the simulation for  $\beta = 6.57$  was performed with a single smearing level, yielding less control over excited state contaminations. As a result the error in  $r_0/a$  seems to be somewhat underestimated. Although the statistical significance of this small effect is not clear, we decided to use our new data for  $\beta = 6.57$  instead.

**Figure 2.5:** Interpolation of  $r_0/a$ .

then one is justified to attempt a phenomenological representation of  $(\ln(a/r_0))$  as a polynomial in  $\beta$ . In order to avoid cancellations in the fit parameters, it is convenient to shift the value of  $\beta$  to  $(\beta - x)$ , such that  $(\beta - x)$  is small in the interval of couplings that we considered. We then chose the following ansatz:

$$\ln(a/r_0) = \sum_{k=0}^p a_k (\beta - 6)^k, \quad (2.78)$$

and found that

$$\begin{aligned} \ln(a/r_0) &= -1.6804 - 1.7331(\beta - 6) + 0.7849(\beta - 6)^2 - 0.4428(\beta - 6)^3, \\ &\text{for } 5.7 \leq \beta \leq 6.92, \end{aligned} \quad (2.79)$$

is an excellent approximation to the MC results, as shown in Fig. 2.5. The accuracy of  $r_0/a$  in eq. (2.79) is about 0.5% at low  $\beta$  decreasing to 1% at  $\beta = 6.92$ .

## 2.5 Continuum force and potential

One can now determine the continuum force and potential by extrapolation of the MC-results at finite values of the lattice spacing to the continuum, which corresponds to  $a = 0$  ( $\beta = \infty$ ).

As mentioned in sect. 2.4.5, the lattice results are first interpolated in  $r$ , then renormalized dimensionless quantities are evaluated. If the lattice spacing is small enough, one expects renormalized dimensionless quantities to be independent of  $\beta$  (and thus of  $a$ ); this feature is called *scaling*. Any deviation from this scaling behavior is due to the presence of lattice artifacts. The size of the scaling violating corrections will

in general depend on which quantities are being considered.

In order to approach the continuum limit, one needs a theoretical understanding of the lattice artifacts; the standard framework for this discussion is Symanzik's effective theory, which is expected to give the asymptotic expansion of suitable lattice observables in integer powers of the lattice spacings (up to at least logarithmic further suppressions as  $a \rightarrow 0$ ) in an asymptotically free theory [30, 82]. In the 2-dimensional  $O(3)$   $\sigma$  model it predicts the expansion to start at order  $a^2$  but unexpectedly numerical results are described better by a dominant linear term in  $a$  for a range of lattice spacing [83]. While there is no evident contradiction with the result of an analysis à la Symanzik which is supposed to describe the *asymptotic* behavior, the standard picture should be tested in 4-d gauge theories and QCD as much as possible.

The leading artefacts in potential differences are expected to be  $O(a^2)$ , but this is not obvious since the potential is usually defined in terms of a Wilson loop, which does not fall into the category of correlation functions of local fields discussed by Symanzik.

In [84] a clean argument supporting this expectation is given: in short, the motivation is that the heavy quark effective theory [85] formulated on the lattice is  $O(a)$ -improved without adding any additional operators to the Lagrangian [86]. The potential is an energy of the effective theory and thus has no linear  $a$ -effects. Of course, for this statement to be meaningful, the self energy has to be eliminated by considering potential differences or the force.

Figure 2.6 shows the dependence of the force in units of  $r_c$  on the resolution for some selected values of the separation  $r$ . Fitting <sup>11</sup>

$$r_c^2 F(r) = r_c^2 F(r)|_{a=0} [1 + s(r/r_c) \times (a/r_c)^2] \quad (2.80)$$

for fixed  $r/r_c$  and for  $r/a > 2$ , the slope  $s$  is statistically not significant throughout our range of  $r$  and  $\beta$ . Our statistical precision allows to quote

$$|s(r/r_c)| < 1 \quad \text{for } 0.4 \leq r/r_c \leq 1. \quad (2.81)$$

Of course this  $1\text{-}\sigma$  bound is valid only when all details are as discussed above, in particular eqs. (2.48,2.52) are used to define the force at finite  $a$ . If the naive form  $r' = r - \frac{a}{2}$  is employed instead, the corresponding slopes  $s$  become rather large, as can be seen in the figure.

A similar statement ( $r/a > 2$ ),

$$r_0^2 F(r) = r_0^2 F(r)|_{a=0} [1 + s(r/r_0) \times (a/r_0)^2] , \quad (2.82)$$

$$|s(r/r_0)| < 1.2 \quad \text{for } 0.5 \leq r/r_0 \leq 1.5 , \quad (2.83)$$

can be made for larger  $r$ .

One can conclude that using a tree-level improved definition of the force, lattice spacing effects are below the level of our small statistical errors when one restricts oneself to  $r > 2a$  and to the lattice spacings considered here. By contrast, with a

<sup>11</sup>In general, the discretization errors parametrized by  $s$  depend also on the orientation  $\vec{r}/r$ , which in our calculation was fixed to  $\vec{r}/r = (1, 0, 0)$ , however.

**Figure 2.6:** Continuum extrapolation of  $r_c^2 F(xr_c)$ , for  $x = 0.4, 0.5, 0.9$  from top to bottom and of  $r_0^2 F(xr_0)$ , for  $x = 0.5, 0.6, 1.5$  from top to bottom. The data are from our new computations and from [73]. Filled circles correspond to the naive value  $r' = r - \frac{a}{2}$  instead of eq. (2.52).

naive midpoint rule for the force, the  $a$ -effects are quite sizeable. The difference is by construction a pure power series in  $a$ , starting with  $a^2$ . For  $r > 2a$  this series is well approximated by the leading term. Thus both data sets in Fig. 2.6 contain the same essential information: full compatibility with Symanzik’s theory of discretization errors.

The continuum force is plotted in Fig. 2.7 using eq. (2.73) to combine the two regimes of  $r$ . Some data at finite  $\beta$  (in particular  $\beta = 6.4, 6.92$ ) are included in the figure. In these cases we used our “bounds” on  $s$  to estimate that the discretization errors are smaller than the statistical ones. One can observe that for large distances the force reaches a constant value, as sign of the confinement; a detailed discussion on the comparison with the predictions of the perturbative theory and the bosonic string model will be presented in section 2.7.

The potential contains the same physical information as the force but statistical and systematic errors in the lattice determination are different. From the non-perturbative point of view, the potential is defined only up to a constant, which represents the self energy of the static quark-antiquark pair. To eliminate this self energy contribution we consider  $V_I(r) - V_I(r_c)$ , where we apply the same improvement as for the force,

$$V_I(d_I) = V(d) , \quad (4\pi d_I)^{-1} = G(d, 0, 0). \quad (2.84)$$

In analogy to  $r_I$ ,  $d_I$  is defined such that the potential has no lattice artifacts when evaluated at three level. The continuum extrapolation is performed exactly as for the force. In this case the slopes,  $s(r/r_c)$ , defined as above are statistically significant for both our smallest distances ( $r \approx 0.3r_c$ ) and the largest one ( $r \approx 1.5r_0$ ). As a consequence, at small  $r$  the combination  $[V_I(r) - V_I(r_c)]r_c$  has about 1% discretiza-

**Figure 2.7:** The force in the continuum limit and for finite resolution, where the discretization errors are estimated to be smaller than the statistical errors.

**Figure 2.8:** Continuum extrapolation of  $V_I(r)$ , for  $r/r_0 = 1.5, 0.6, 0.5$  on the left hand side and for  $r/r_c = 0.9, 0.4, 0.3$  on the right hand side.

tion errors at  $\beta = 6.92$  while in the large distance region these errors go up to 1% in  $[V_I(r) - V_I(r_c)]r_0$  at  $\beta = 6.4$ . These are the  $\beta$ -values corresponding to the smallest lattice spacings available in the two different regions.

One concludes that here, small  $a$ -effects could also be observed for the tree level improved definition. As for the force -but not shown in the figure- the standard definition without tree-level improvement shows quite large  $a$ -effects compatible with an  $a^2$ -behavior, and this confirms again the validity of the Symanzik picture.

The continuum potential is plotted in Fig. 2.9, with some data at finite  $\beta$ . In this figure the statistical as well as the discretization errors are below the size of the symbols. The results for continuum force and potential are listed in Table 2.7.

## 2.6 Comparison with perturbation theory

The perturbative expansion in the coupling  $\alpha_s$  is the most important theoretical tool for analyzing strong interactions effects in high energy scattering experiments. In practical applications however, in particular in the determination of the running coupling itself, it is tempting to apply the perturbative series already where the coupling is not so small to justify the applicability of perturbation theory. Popular examples are the determinations for  $\alpha_s$  from  $\tau$ -lepton decays and the perturbative evolution of deep inelastic scattering structure functions starting at a renormalization point below 1 GeV. In order to establish the reliability of perturbation theory, it would be very desirable to study such processes systematically as functions of the energy, but either they involve a fixed energy ( $\tau$ -decays, hadronic  $Z$ -decays) or the precision is not sufficient over a larger energy range (deep inelastic scattering,  $e^+e^-$  total cross section, Adler function). The main phenomenological test of perturbation theory, therefore, is the overall consistency of the determination of  $\alpha_s$  from different processes (see [13]).

Complementary information may be obtained from observables that can be computed via lattice QCD, like the static quark potential. As already mentioned in

**Figure 2.9:** The static potential in the continuum limit.

section 2.2, in perturbation theory the potential has been computed at two loops, but at the same time the usefulness of perturbation theory even at distances as short as 0.1 fm has been questioned [53, 87]. Comparison between the perturbative prediction and the non-perturbative results will show that this is a question of a suitable renormalization scheme. When the most natural scheme, the  $\overline{\text{MS}}$  defined in terms of the force eq. (2.17) is adopted, perturbation theory is well behaved at such distances. This is a rather stringent test of perturbation theory, since we can use the knowledge of the  $\Lambda$ -parameter together with the RG perturbative evaluation of the coupling, which predicts not only the scale dependence of the coupling, but also its absolute value.

In an exploratory investigation, concentrated on the question, whether there are "large non-perturbative" terms in the potential at short distances [23] they had been argued to exist [24].

In particular, non-perturbative ultraviolet contributions to the running coupling proportional to  $\Lambda^2/q^2$  were investigated. In the case of the static quark potential, such a contribution to the running coupling results in a term proportional to the quark separation,  $r$ .

The first important step to start our analysis is to give a definition of "large non-perturbative term". We assume that the following is understood by this statement.

1. A certain quantity, here the potential  $V(r)$ , is considered in a region where its perturbative expansion looks well behaved, i.e. the  $n$ -loop contribution is a small correction and significantly smaller than the  $(n-1)$ -loop contribution (unless the latter is accidentally small itself).
2. The difference between the full non-perturbative observable and the truncated

perturbative series is much larger than the last term in the series.

With such a definition, necessarily somewhat phenomenological in character, we shall demonstrate that there are definitely no large non-perturbative terms in the potential. To the contrary, perturbation theory works remarkably well where criterion 1. is satisfied.

In section 2.2 we established that for  $\alpha_{q\bar{q}}$  this condition is valid up to distances  $r \sim 0.25$  fm, corresponding to  $\alpha_{q\bar{q}} \lesssim 0.3$ . In Fig. 2.10 we compare the perturbation theory predictions for  $\alpha_{q\bar{q}}(r)$  with our non-perturbative results, which were obtained from the force extrapolated to the continuum limit by the simple relation

$$\alpha_{q\bar{q}}(r) = \frac{3}{4}F(r)r^2. \quad (2.85)$$

We included also additional points at finite  $\beta$ , where the discretization errors were estimated to be smaller than the statistical ones. The 3-loop RG expression with  $\Lambda_{\overline{\text{MS}}}$  at the upper end of the error bar of eq. (2.36) is in very close agreement with the non-perturbative coupling. In fact the agreement extends up to values of  $\alpha_{q\bar{q}}$  where perturbation theory is not to be trusted a priori. For  $\alpha_{q\bar{q}} \lesssim 0.3$  criterion 1. is satisfied and there is no evidence for non-perturbative terms in this region.

**Figure 2.10:** Running coupling in the  $q\bar{q}$  scheme. Results for the continuum limit as well as additional points at finite  $\beta$ , corresponding to finite lattice spacing are shown. The perturbative curves use  $\Lambda_{\overline{\text{MS}}}r_0$  from [15] with the dotted lines corresponding to the  $1\text{-}\sigma$  uncertainties of this number.

One can perform an additional test by considering the relation between  $\alpha_{\text{SF}}(\mu)$  and  $\alpha_{q\bar{q}}(\mu)$  at finite  $\mu$ : using eq. (2.25) and the coefficient in Table 2.4, we define the 3-loop expression<sup>12</sup>

$$h(\alpha_{\text{SF}}(\mu)) = \alpha_{\text{SF}}(\mu) + 1.336 [\alpha_{\text{SF}}(\mu)]^3 \quad (2.86)$$

<sup>12</sup>Note that the term proportional to  $\alpha_{\text{SF}}(\mu)^2$  is not present due to our specific choice of the relative scale factor  $s$ , eq. (2.33).

such that

$$\alpha_{\text{q}\bar{\text{q}}}(\mu) = h(\alpha_{\text{SF}}(\mu/s_0)) + O([\alpha_{\text{SF}}(\mu/s_0)]^4). \quad (2.87)$$

Then the non-perturbative values of  $\alpha_{\text{q}\bar{\text{q}}}(\mu)$  and  $h(\alpha_{\text{SF}}(\mu/s_0))$  are compared in Fig. 2.11. If the higher order terms in eq. (2.87) are negligible, the two different quantities should agree. At  $\alpha_{\text{q}\bar{\text{q}}}(\mu) \approx 0.3$  a difference is visible but this is only about  $3 \times \alpha^4$ , not so far from the expected size of the next order term in the series. At  $\alpha_{\text{q}\bar{\text{q}}}(\mu) \approx 0.2$ , the difference  $\alpha_{\text{q}\bar{\text{q}}}(\mu) - h(\alpha_{\text{SF}}(\mu/s_0))$  is not significant at all. We conclude that also in eq. (2.87) a large non-perturbative term at short distances is excluded.

One has to note here that the static quark potential defined through the Wilson loop suffers from infrared (IR) divergences when computed at finite orders of perturbation theory [21]; this is related to the non-Abelian nature of SU(3), which allows massless gluons to self-interact at arbitrarily small energy scales. The leading IR singularities in the Wilson loop were argued to exist at order  $\alpha_s^4$  in [22]. These singularities can be regulated by a resummation, and the result is that the next order correction in eq. (2.87) is formally enhanced by a logarithm of  $\alpha$  and reads [21, 22, 87]

$$(A \log(\alpha) + B)\alpha^4. \quad (2.88)$$

While  $A = \frac{9}{4\pi}$  has been calculated [88, 89],  $B$  is not known. The  $A\alpha^4 \log(\alpha)$  term by itself constitutes a small correction in the Fig. 2.11, which would slightly enlarge the difference between  $h(\alpha_{\text{SF}}(\mu/s_0))$  and  $\alpha_{\text{q}\bar{\text{q}}}(\mu)$ .

Finally, Fig. 2.12 shows the static potential itself compared to different perturbative approximations. In this case we can not use the coupling  $\alpha_{\bar{\text{V}}}(\mu)$  for the comparison, because it does not have a non-perturbative definition, as already mentioned in Sect. 2.2. The potential is defined up to a constant, which has to be eliminated for example by considering the quantity

$$[V(r) - V(r_c)]r_0,$$

where  $r_c$  is related to  $r_0$  by eq. (2.73).

Full line and short dashes are given by integrating the force

$$V(r) = V(0.3r_c) + \int_{0.3r_c}^r dy F(y), \quad F(r) = C_F r^2 \alpha_{\text{q}\bar{\text{q}}}(1/r) \quad (2.89)$$

with the 3-loop and 2-loop RG-solution for  $\alpha_{\text{q}\bar{\text{q}}}$ . The free constant was fixed such that at  $r = 0.3r_c$  the perturbative prediction coincides with the non-perturbative result. This comparison is meaningful only with the assumption that the perturbative expansion is well behaved at that distance. Since we know that the 3-loop RG-solution for  $\alpha_{\text{q}\bar{\text{q}}}$  is accurate, this also holds for  $V(r)$  computed through eq. (2.89). Again, the full line moves very close to the data points ( $r < 0.5r_0$ ), when  $\Lambda_{\overline{\text{MS}}}r_0$  at the upper end of the error bar is inserted.

Another possibility is to compare the potential directly with eq. (2.16) by using the RG-solution for  $\alpha_{\bar{\text{V}}}$ . From the considerations of section 2.2 we expect that perturbation theory is applicable only up to  $\alpha_{\bar{\text{V}}} \lesssim 0.15$ ; by solving the RG equation in

the  $\overline{V}$  scheme with the central value eq. (2.36), one observes that at  $r = 0.3r_c$  one has  $\alpha_{\overline{V}}(2\text{loop}) \simeq 0.28$ ,  $\alpha_{\overline{V}}(3\text{loop}) \simeq 0.9$ . This means that one is already at those small distances outside the region where perturbation theory can be trusted. The long-dashed line in Fig. 2.12 represents eq. (2.16) with the 2-loop RG solution for  $\alpha_{\overline{V}}$ ; we decided not to use the 3-loop prediction due to the fact that the coupling is very large at the distance  $r \sim 0.15r_0$ . As it was to be expected due to the missing stability of this perturbative expression, it fails in describing the non-perturbative potential.

A similarly bad perturbative expression is the direct expansion of the potential in terms of  $\alpha_{\overline{\text{MS}}}$ ; for this comparison we used the matching equation eq. (2.25), with  $S' = \overline{V}$ ,  $S = \overline{\text{MS}}$ . For the same reason explained before, we decided to use the 2-loop RG prediction for  $\alpha_{\overline{\text{MS}}}$ . The dotted line corresponds to the choice  $s = 1$  in eq. (2.25), while the dashed-dotted line corresponds to  $s = s_0$  (eq. (2.33)).

**Figure 2.11:** Test of eq. (2.25). The uncertainty in the combination  $\mu r_0$  has been translated into an uncertainty for  $h(\alpha_{\text{SF}}(\mu/s_0))$  and  $\alpha_{\text{q}\overline{\text{q}}}(\mu)$ . The non-perturbative values for  $\alpha_{\text{SF}}(\mu)$  are constructed from the data of [15]. Errors are smaller than the size of the symbols.

In summary, care has to be taken which perturbative scheme is adopted to describe the potential. However, perturbation theory does its best in the following sense. As usual in an asymptotic expansion, one should first investigate the apparent "convergence" by comparing subsequent orders and checking that they decrease significantly. If this is not the case, one is obviously outside the domain of applicability of perturbation theory or has chosen a bad truncation (scheme). According to this criterion the  $\beta$ -function in the  $\text{q}\overline{\text{q}}$ -scheme may be trusted up to  $\alpha_{\text{q}\overline{\text{q}}} \approx 0.3$ . Other truncations of perturbation theory for the potential are applicable for much smaller values of the coupling only; for example, a scheme with a large 3-loop coefficient such as  $\overline{V}$  is of no use in the region  $\alpha > 0.15$ . Therefore, perturbation theory

**Figure 2.12:** The potential compared to different perturbative expressions.  $r_c$  is related to  $r_0$  by eq. (2.73).

suggests that the  $q\bar{q}$  scheme should be used in order to obtain a reliable perturbative expression. The comparison with non-perturbative results, obtained in the continuum limit of lattice simulations ( $N_f = 0$ ), does confirm that such a perturbative analysis is a good guideline -at least in the case at hand. At rather high values of the coupling,  $\alpha \approx 0.3$ , we only expect that the 3-loop perturbative prediction is good to within about 10% and indeed in Fig. 2.11 one sees explicitly that the truncated perturbative series has errors of this order. Similar results have been found for the coupling obtained with  $N_f = 2$  in the SF-scheme [90, 19].

If one considers the full QCD, the first observation is that, compared to  $N_f = 0$ , the relevant perturbative coefficients,  $b_2$  and  $f_2(s_0)$  which are listed in Table 2.1 and Table 2.2, are roughly a factor two smaller in magnitude for  $N_f = 3$ . This suggests that including the quarks the perturbative prediction for the potential computed through  $\alpha_{q\bar{q}}$  is also applicable up to  $\alpha \approx 0.3$  and furthermore in full QCD the issue of the appropriate scheme is somewhat less important. A direct lattice QCD check of these expectations is not possible at present and one has to boldly generalize from the  $N_f = 0$  case. In addition, these remarks apply only to the massless theory (mass effects were not investigated). Current phenomenological research concentrates on application of a velocity dependent potential beyond the static limit for applications to top-quark physics [91]. On the one hand, in this application the potential is needed for quite short distances, where perturbation theory is intrinsically more precise [92], on the other hand, with the velocity entering as a new scale, this represents a more difficult multiscale problem. Indeed the renormalization group has already been applied to deal with this complication [93].

Nevertheless, the lessons learnt in our investigation may be useful in this context as well; the type of renormalization group improvement which we found to increase the

reliability of perturbation theory has not been applied in [91] so far.

## 2.7 Comparison with the bosonic string model

Although we concentrated on the evaluation of the potential at short and intermediate distances, where the validity of the string picture described in section 2.3 is a priori not expected, it is interesting to compare our results with this model.

If one assumes that the bosonic string picture described is valid already at  $r = r_0$ , at next-to-leading order (NLO) in the effective theory one obtains the parameter free predictions

$$V(r) = \sigma r - \frac{\pi}{12r} + \text{const}, \quad (2.90)$$

$$F(r) = \sigma + \frac{\pi}{12r^2}, \quad (2.91)$$

where  $\sigma$  is fixed by the eq. (2.46),

$$\sigma r_0^2 = 1.65 - \frac{\pi}{12}. \quad (2.92)$$

In Fig. 2.13 one can see that eq. (2.90) (dotted line) is in excellent agreement with our results for  $r \geq 0.8r_0$ .

As already mentioned in sec. 2.3, in the same region of  $r$ , excited potentials do not at all follow the expectations from the effective bosonic string theory. This may suggest that the agreement with eq. (2.90) is rather accidental. In any case one would expect corrections to this formula to be negligible only for much larger  $r$ .

If one includes the higher order correction (NNLO) eq. (2.42) founded in [29] (solid line), one can notice that at short distances the agreement is worse, while at our largest distances it seems to be better, although our precision here is not good enough to make any definitive statement. This fact seems to confirm that the agreement at short distances is coincidental.

The fact that at short distances the NLO prediction is able to describe the data better than the NNLO is not surprising: we are dealing with an asymptotic expansion in a region where the expansion parameter  $\frac{1}{r}$  is large. Under these circumstances it is well known that the introduction of higher order terms in the series do not necessarily improve a prediction and can even make it worse.

Figure 2.14 shows the same comparison for the force; finally, in Fig. 2.15 we compared our results for large  $r$  with the ones obtained by Lüscher and Weisz for their largest  $\beta$  [29]. One observes that the algorithm for the exponential error reduction [64] adopted there is highly necessary to obtain a good precision of the data. On the contrary, with our results for  $r > 1.2r_0$  we would not be able to evaluate the correction  $b$  in eq. (2.42).

From this discussion one can conclude that the understanding of the long range properties of the static quark potential and the testing of bosonic string model is still an important task and requires the employment of advanced numerical techniques in order to have a reliable measurement of the observables in that range.

**Figure 2.13:** The potential compared with the parameter-free prediction of the bosonic string model, from eq. (2.40) (dashed line) and eq. (2.42) (solid line). The constant term has been fixed such that the predictions coincide with the non-perturbative results at  $r = 0.9r_0$ .

**Figure 2.14:** The force compared with the parameter-free prediction of the bosonic string model. The dashed line represents the string prediction at leading order eq. (2.91), while the solid line include the correction eq. (2.42) with  $b = 0.04\text{fm}$ .

**Figure 2.15:** The force compared with the bosonic string model at large distances. The points correspond to our computation of the force extrapolated to the continuum, while the triangles are taken from [29] for  $\beta = 6.0$ .

## Chapter 3

# Scaling properties of RG actions: the critical temperature

Starting from the Wilson formulation of Yang Mills theory on the lattice, eq. (1.5), it was observed that for many physical observables it leads to sizeable discretization errors. To perform a continuum extrapolation of the physical quantities of interest usually requires a big computational effort which is often not practicable. Therefore it is highly desirable to use a lattice formulation which reduces the discretization errors to have a more reliable estimation of physical quantities. As we have seen, the Wilson gauge action shows leading lattice artefacts of order  $O(a^2)$ ; by formulating fermions on the lattice in general one expects corrections starting already at  $O(a)$ . For this reason in recent years most of the efforts were spent to improve the fermionic action in view of unquenched simulations.

For example, by following the Symanzik approach, one can attempt to cancel all lattice effects of order  $a$ ; this development started some time ago [32, 94] and the coefficients multiplying the various  $O(a)$  counterterms in the improved theory have been determined non-perturbatively [95, 96, 97].

In any case it turns out that also the gauge part plays a very important rôle, and the question which is the most convenient gauge action to adopt has been often addressed.

In particular, the Iwasaki action has been used by the CP-PACS collaboration [37] for the most advanced computation of light hadron spectrum. Moreover, the RG improved actions have been considered as candidates to be used in the next simulations on Ginsparg-Wilson/domain wall fermions; interesting features were observed for these actions, as the suppression of small instantons and dislocations and a possible remedy of the problem of residual chiral symmetry breaking for domain wall fermions [98, 99].

This increasing interest in alternative gauge actions motivates more investigations into their properties, starting from the basic ones, like universality and scaling behavior. There are in principle several quantities that one can use to quantify the lattice artifacts and to test universality by comparing the results with the plaquette action known in the literature. The renormalized observables that we have considered are  $T_c r_0$ , where  $T_c$  is the deconfining phase transition temperature, and  $m_G r_0$ , where  $m_G$  represents the glueball mass and will be discussed in the next chapter.

In particular, our study required the computation of the scale  $r_0/a$  for RG actions, which was up to now not present in the literature.

In this chapter the physical observables will be defined, the details of the lattice calculation will be explained with particular emphasis on the possible difficulties and the results will be discussed.

### 3.1 The critical temperature $T_c$

In chapter 1 it has been pointed out that Euclidean quantum field theory in the functional integral formalism, in particular its lattice regularized version, is formally equivalent to a system of classical statistical mechanics in four dimensions.

Complementary to this, another point of view makes use of Hamiltonian formalism and the transfer matrix (see appendix B); from eq. (B.15), eq. (B.18) one obtains that for a lattice with  $N_t$  points in the time direction and  $N_s$  points in the three space-directions (we assume for simplicity to be the same for all the space directions)<sup>1</sup>, the partition function of the system is given by

$$Z = \text{tr} (e^{-a N_t \mathbb{H}}). \quad (3.1)$$

In the limit  $N_s, N_t \rightarrow \infty$  this corresponds to a 4-dimensional quantum field theory at physical temperature  $T = 0$ .

For several applications, for example the study of hot hadronic matter or early universe, it would be desirable to consider quantum field theory at finite physical temperature  $T$  also.

In quantum statistical mechanics the partition function of a finite-temperature system is defined by

$$Z\left(\frac{1}{T}\right) = \text{tr} (e^{-\frac{1}{T} \mathbb{H}}), \quad (3.2)$$

where the Boltzmann factor has been set equal to 1, and the thermal expectation value of any observable  $A$  is given by

$$\langle A \rangle = \frac{1}{Z\left(\frac{1}{T}\right)} \text{tr} (e^{-\frac{1}{T} \mathbb{H}} A). \quad (3.3)$$

Comparing these expressions with eq. (3.1) and eq. (1.8), one recognizes that a  $N_s^3 N_t$  lattice with periodic boundary conditions in the time direction can be regarded as a system of finite volume  $V = (N_s a)^3$  at finite temperature  $T$ , which is related to  $N_t$  by

$$\frac{1}{T} = N_t a. \quad (3.4)$$

The thermodynamic limit corresponds to  $N_s \rightarrow \infty$ ; in order to approximate this condition in a simulation in a finite spatial volume, one should respect the relation

$$N_s \gg N_t. \quad (3.5)$$

---

<sup>1</sup>In order to avoid notational confusion, in this chapter we will use  $T$  for the temperature, and  $N_t$  for the time-extent of the lattice.

It was pointed out in [100, 101] that pure Yang-Mills theory undergoes a first order phase transition at some temperature  $T_c$ ; below the critical temperature one has the confined phase, while the high temperature region is characterized by a gluon plasma with freely moving but still interacting gluons.

The Polyakov loop <sup>2</sup>

$$P(\vec{x}) = \text{Tr} \prod_{x_0=0}^{N_t-1} U(x, 0) \quad (3.6)$$

can be interpreted as an order parameter for the deconfining phase transition: in the deconfined phase it assumes a non-vanishing expectation value  $\langle P(\vec{x}) \rangle \neq 0$ .<sup>3</sup>

In full QCD the low temperature phase corresponds to the usual hadronic QCD vacuum, and the high temperature phase is a quark-gluon plasma where the characteristic low energy features, like confinement and spontaneous chiral symmetry breaking are lost, and the short distance behavior of matter is governed by the asymptotic freedom of QCD (see [102] for a review).

The first non-perturbative lattice determinations of  $T_c$  can be found in [103]; the general strategy consists of keeping the relation in eq. (3.4) fixed while varying the gauge coupling  $\beta$  and therefore implicitly the lattice spacing  $a$ . In this way one moves the lattice system through the phase transition obtaining

$$\frac{1}{T_c} = N_t a(\beta_c). \quad (3.7)$$

There are several methods for determining the critical coupling  $\beta_c$ ; it is desirable to refer to a definition based on a quantity with a definite finite size scaling behavior, for instance the Polyakov loop susceptibility, defined as

$$\chi = V(\langle |P^2| \rangle - \langle |P| \rangle^2), \quad V = N_s^3. \quad (3.8)$$

In the thermodynamic limit, the susceptibility has a delta-function singularity corresponding to a first order phase transition. On a finite lattice the singularity is rounded off and one observes a peak for  $\beta_c(V)$ . The critical coupling for each value of  $N_t$  can be extrapolated to the thermodynamic limit using the finite size scaling law for a first order phase transition,

$$\beta_c(N_t, N_s) = \beta_c(N_t, \infty) - h \left( \frac{N_t}{N_s} \right)^3, \quad (3.9)$$

where  $h$  is considered to be a universal quantity independent of  $N_t$  [104].

In addition to its intrinsic importance as a fundamental non-perturbative prediction,  $T_c$  provides also a useful quantity to study the lattice artifacts for different

<sup>2</sup>Note that here “Tr” indicates the trace on the gauge group  $SU(N)$ , while in eq. (3.1) “tr” is the trace in the Hilbert space.

<sup>3</sup>Strictly speaking, only the Polyakov loop correlator  $\langle P(\vec{x})P^\dagger(\vec{0}) \rangle$  has a physical meaning and can be used as an order parameter. Assuming cluster decomposition at large distances one obtains  $\langle P(\vec{x})P^\dagger(\vec{x}) \rangle \sim_{|\vec{0}| \rightarrow \infty} \langle |P| \rangle^2$ , and one can notice that the phase of  $\langle P \rangle$  is not a physically measurable quantity.

**Figure 3.1:**  $T_c/\sqrt{\sigma}$  as function of  $1/N_t^2$  for different actions, from [50]. By “RG improved” is meant here the Iwasaki action.

$N_t$	$\beta_c$ Wilson [104]	Iwasaki [38]	DBW2 [106]

4	5.6925(2)	2.2879(11)	0.82430(95)
6	5.8941(5)	2.5206(24)	0.9636(25)
8	6.0624(12)	2.7124(34)	
12	6.3380(23)		

**Table 3.1:** The critical coupling from the literature for Wilson, Iwasaki and DBW2 actions.

gauge actions and to test universality.

In order to investigate the scaling properties, one has to measure a dimensionful quantity like  $r_0$  at zero temperature for  $\beta = \beta_c$  and then build the renormalization group invariant combination  $r_0 T_c$ . For known values of  $\beta_c$  at given  $N_t$  for different actions one can refer to [105, 104, 38, 106, 50]; for Wilson, Iwasaki and DBW2 actions, these values are collected in Table 3.1.

Instead of using  $r_0$  to set the scale, the results that are available in the literature are mostly related to the quantity  $T_c/\sqrt{\sigma}$ ; they are reported in Table 3.2, where the continuum extrapolations are from a reanalysis by Teper [107]. Figure 3.1 collects the results for Wilson, Iwasaki, DBW2, Symanzik tree level and FP action, and was taken from [50] which reports the latest evaluation of  $T_c/\sqrt{\sigma}$  (FP action).

The first observation from Fig. 3.1 is that from this specific quantity it is not possible to arrive at precise conclusions about the discretization errors for different actions.

Furthermore, one notices that for the Iwasaki and the Wilson action a difference of order  $2\sigma$  in the continuum results is observed. The most drastic explanation for this

action	$N_t$	$T_c/\sqrt{\sigma}$
Wilson [104]	$\infty$	0.630(5)
Iwasaki [38]	$\infty$	0.651(12)
DBW2 [106]	$\infty$	0.627(12)
Sym. tree level [104]	$\infty$	0.634(8)
1 loop tadpole impr. [108]	$\infty$	0.659(8)
FP [50]	4	0.624(7)

**Table 3.2:** Results for the deconfining temperature in units of the string tension from different actions [107].

discrepancy could be a violation of universality, but this scenario seems unrealistic; a more natural explanation is that the string tension is difficult to determine, as already pointed out in chapter 2, and it is preferable to use  $r_0$  to reliably set the scale in pure Yang-Mills theory.

For the Wilson action, the values of  $r_0/a$  corresponding to the critical couplings can be easily obtained by the parametrization formula [73]<sup>4</sup>

$$\ln(a/r_0) = -1.6805 - 1.7139(\beta - 6) + 0.8155(\beta - 6)^2 - 0.6667(\beta - 6)^3. \quad (3.10)$$

For the Iwasaki and DBW2 action there was up to now no precise evaluation of  $r_0/a$  and we decided to perform new numerical simulations with this purpose.

## 3.2 Evaluation of $r_0/a$ for RG actions

For the evaluation of  $r_0/a$  we followed the same procedure as for the usual plaquette action, as described in 2.4.1. We constructed Wilson loop correlation matrices employing smearing techniques and multi-hit methods<sup>5</sup>. We will not repeat here the description of the procedure, but mention only the difficulties with respect to the plaquette case. The simulation parameters are reported in Table 3.3 and Table 3.4.

### 3.2.1 Effective potential

We adopted the same smearing operator as for the Wilson action eq. (2.54), with  $M = 4$ ,  $\alpha = \frac{1}{2}$  and the same condition for the smearing levels eq. (2.57).

For the Wilson action it is possible to define a positive transfer matrix and hence a well-defined Hamiltonian; from eq. (2.8) one notices that the contributions to the spectral decomposition of correlation functions are always positive. On the contrary, for the Iwasaki and DBW2 action, due to the violation of physical positivity

<sup>4</sup>We decided to use the parametrization formula of [73] instead eq. (2.79), which is valid for larger range of  $\beta$  but less accurate.

<sup>5</sup>Due to the presence of  $(1 \times 2)$  plaquettes in the RG actions, not every temporal link appearing in the Wilson loop can be substituted by the one obtained with the multi-hit integration. We applied the multi-hit procedure only on alternating links so that two multi-hit links can not belong to the same  $(1 \times 1)$  or  $(1 \times 2)$  loops.

**Figure 3.2:** The effective potential as function of  $t$  for  $r \approx r_0$  ( $r_0 \sim 4 - 5$ ) for the Wilson plaquette action and for the RG-improved Iwasaki and DBW2 action.

described in appendix B, one expects also negative contributions, so that the plateau in the effective potential is reached from below. This fact spoils the possibility to find an unambiguous criterion to define the "optimal" smearing: the ability of the smearing operator to suppress the higher order excitations can be tested only for  $t \gg t_{min}$ , where  $t_{min}$  is estimated in eq. (B.35).

We started our analysis by observing the time-dependence of the effective potential for the different smearing levels. Figure 3.2 shows the effective potential

$$aV(r) = -\ln \left( \frac{C_{22}(t)}{C_{22}(t-a)} \right) \quad (3.11)$$

evaluated from the diagonal elements of the correlation matrices eq. (2.59) for  $l = m = 2$ , which corresponds to what was estimated to be the optimal smearing for the Wilson action. Notice that the negative contributions for the RG actions are strongly evident and, as expected, they disappear starting from a certain  $t$  which becomes larger as the coefficient  $c_1$  in the action increases.

One observes however a quite satisfactory plateau in the effective potential, starting at sufficiently large  $t$ . We decided to extract the potential from eq. (3.11) without applying the variational method, which is mathematically founded on the positivity of the correlation matrix  $C_{lm}$  at a certain  $t = t_0$ ; this condition is verified only for  $t_0 \gg t_{min}$ , but on the other hand  $t_0$  can not be arbitrarily large because of the statistical errors, which increase with  $t$ , that make the inversion of  $C_{lm}$  impracticable. We extracted the potential from eq. (3.11) at  $t/a = (3 - 4)$  and we estimated the

systematic error by taking the difference between this value and what one would obtain extracting the potential at  $(t+a)$ . The systematic errors were linearly added to the statistical one; at small  $r$  the total uncertainty is dominated by the systematic error, while at large distances the situation is in general reversed.

### 3.2.2 The force at tree level

It is interesting to study the force at tree level for different actions, in order to investigate how the continuum limit is approached at small coupling  $\bar{g}$ , where it is legitimate to expect that the tree-level approximation is quite accurate.

Explicitly, the force at tree level is given by [47]

$$\begin{aligned} F_{tree}(r') &= \frac{V_{tree}(r) - V_{tree}(r-a)}{a} \\ &= -\frac{4}{3} \frac{g_0^2}{a} \int_{-\pi}^{\pi} \frac{d^3k}{(2\pi)^3} \frac{\cos(rk_1/a) - \cos((r-a)k_1/a)}{4 \left( \sum_{j=1}^3 \sin^2(k_j/2) - 4c_1 \sum_{j=1}^3 \sin^4(k_j/2) \right)}. \end{aligned} \quad (3.12)$$

Note that for  $c_1 = 0$  one obtains the results already mentioned for the plaquette action eq. (2.50). For the special choice  $c_1 = -1/12$ , which corresponds to the Symanzik tree-level improved action, one finds [47]

$$r'^2 F_{tree}^{sym}(r') = \frac{4}{3} \frac{g_0^2}{4\pi} + \mathcal{O}\left(\frac{a}{r'}\right)^4, \quad (3.13)$$

if  $r' = \sqrt{r(r-a)}$ ; this choice of the action cancels indeed the  $\mathcal{O}(a^2)$  terms at tree level.

In Fig. 3.3 the quantity  $\frac{r'^2}{g_0^2} F_{tree}(r')$  is plotted as function of  $(a/r')^2$  for different actions. As expected, in the limit  $r' \rightarrow \infty$  all curves converge to the classical value  $\frac{4}{3} \frac{1}{4\pi}$ . For the Symanzik tree-level improved action one finds eq. (3.13), that is no  $\mathcal{O}(a^2)$  lattice artifacts in the force. One can notice that the RG actions, in particular the DBW2, show at tree level large lattice artefacts at small  $(a/r')$ . The RG actions should reduce the discretization errors at every order in perturbation theory, but it turns out that at tree level these actions are "overcorrected" and introduce lattice artefacts of the same order or even larger than what is expected with the usual plaquette action. This fact should be considered as a problem if one would for example evaluate the potential at short distances, as we did for the Wilson action in chapter. 2: in particular one should consider the continuum extrapolation with great care, because unless  $a/r$  is very small, one can not be sure to be in the region where the leading discretization errors are quadratic in  $a$ .

For our evaluation of  $r_0/a$ , the force is defined exactly as in sect. 2.4.2; also in this case one can introduce a tree-level improved definition of the force such that

$$F_{tree}(r_1) = \frac{4}{3} \frac{g_0^2}{4\pi r_1^2}, \quad (3.14)$$

with no lattice artefacts at tree level.

From eq. (3.12) one deduces that

$$(4\pi r_1^2)^{-1} = -[G(r, 0, 0) - G(r-a, 0, 0)]/a, \quad (3.15)$$

**Figure 3.3:** The force at tree level for several actions.

where

$$G(\vec{r}) = \frac{1}{a} \int_{-\pi}^{\pi} \frac{d^3k}{(2\pi)^3} \frac{\prod_{j=1}^3 \cos(r_j k_j / a)}{4(\sum_{j=1}^3 \sin^2(k_j/2) - 4c_1 \sum_{j=1}^3 \sin^4(k_j/2))}, \quad (3.16)$$

is the scalar lattice propagator associated to the improved action with coefficient  $c_1$  in the  $(1 \times 2)$  plaquette term. Due to the fact that  $G(\vec{r})$  does not satisfy eq. (C.1) because of the presence of higher derivative terms in the action, it is not possible to use the coordinate space methods described in appendix C;  $r_1$  was then computed solving the integral eq. (3.16) numerically.

$N_s$	$\beta$	$n_l$	$N_{or}$	$N_{meas}$
8	2.1551	0,2,4,6	3	20000
12	2.2879	0,4,9,13	4	4000
24	2.5206	0,12,25,37	8	645
32	2.7124	0,18,36,54	9	370

**Table 3.3:** Simulation parameters for the Iwasaki action for the evaluation of  $r_0$ .

### 3.2.3 Results

Using a local interpolating formula for the force as explained in sect. 2.4.5, we extracted the value of  $r_0/a$  which are reported in Table 3.5 and Table 3.6. For the DBW2 action, besides the three values of  $\beta_c$  known in the literature Table 3.1, we

$N_s$	$\beta$	$n_l$	$N_{or}$	$N_{meas}$
10	0.75696	0,2,4,6	3	12000
12	0.8243	0,4,9,13	4	6000
16	0.9636	0,10,20,30	8	800
24	1.04	0,18,36,54	9	220

**Table 3.4:** Simulation parameters for the DBW2 action for the evaluation of  $r_0$ .

decided to evaluate  $r_0/a$  also for a larger  $\beta = 1.04$ , which should roughly correspond to  $\beta = 6$  for the Wilson action and has been used in quenched simulations [99]. Our results for the potential and the force at finite lattice spacing are collected in the tables A.5 and A.6.

$\beta$	$r_0/a (r_n)$	$r_0/a (r_I)$
2.1551	2.311(5)(9)	2.320(6)(9)
2.2879	3.026(4)(3)	3.026(5)(1)
2.5206	4.535(6)(4)	4.511(8)(1)
2.7124	6.020(15)(25)	5.999(15)(19)

**Table 3.5:**

Results for  $r_0/a$  evaluated at different  $\beta = \beta_c$  for the Iwasaki action, using the naive definition of the force eq. (2.49) or the tree-level improved eq. (3.15).

$\beta$	$r_0/a (r_n)$	$r_0/a (r_I)$
0.75696	2.430(5)(20)	2.225(4)(11)
0.8243	3.129(23)(1)	3.036(17)(4)
0.9636	4.606(13)(17)	4.556(17)(20)
1.04	5.500(29)(7)	5.452(26)(8)

**Table 3.6:** Results for  $r_0/a$  evaluated at different  $\beta$  for the DBW2 action, using the naive definition of the force eq. (2.49) or the tree-level improved eq. (3.15).

The first error contains the statistical uncertainty summed to the systematic one due to the interpolation of the force. The second error is the systematic uncertainty coming from different choices of  $t$  in the effective potential eq. (3.11). One can notice that in some cases the last error is the dominating one.

We can notice that for the DBW2 action the choice of  $r_n$  (eq. (2.49)) or  $r_I$  (eq. (3.15)) in the definition of the force leads to results which can be quite different from each other, above all at small  $r_0/a$ ; we expected this feature by investigating the force at tree level. This ambiguity will make the discussion of the lattice artefacts difficult, because the possible conclusions will depend on which definition of the force one has used and not on intrinsic properties of the action.

For the Iwasaki action the two results are not significantly different.

**Figure 3.4:** Parametrization of  $r_0/a$  for the Iwasaki action, eq. (3.17), using the tree-level improved definition of the force.

### 3.2.4 Parametrization of $r_0/a$

Following the strategy of section 2.4.6, one can attempt a phenomenological parametrization of  $r_0/a$  in the range of couplings that we considered.

For the Iwasaki action the four values of  $r_0$  (obtained by adopting  $r_I$ ) were fitted in the form

$$\ln(a/r_0) = c_1 + c_2(\beta - 3) + c_3(\beta - 3)^2, \quad (3.17)$$

yielding the numerical results

$$c_1 = -2.1281, \quad c_2 = -1.0056, \quad c_3 = 0.6041. \quad (3.18)$$

in the range  $2.1551 \leq \beta \leq 2.7124$ .

The results and the fit formula are shown in Fig. 3.4; the accuracy is about 0.6% at  $\beta = 2.1551$  and decrease to 0.8% at  $\beta = 2.7124$ .

For the DBW2 action we have obtained a good accuracy by using a four-parameter fit

$$\ln(a/r_0) = d_1 + d_2(\beta - 1) + d_3(\beta - 1)^2 + d_4(\beta - 1)^3, \quad (3.19)$$

with

$$d_1 = -1.6007, \quad d_2 = -2.3179, \quad d_3 = -0.8020, \quad d_4 = -19.8509, \quad (3.20)$$

for the range  $0.75696 \leq \beta \leq 1.04$ , where the results always refer to the tree-level improved definition of the force. The accuracy is between 0.6% at lower  $\beta$  and 0.8% at higher  $\beta$ ; it is practically given by the statistical accuracy and the fit is plotted

**Figure 3.5:** Parametrization of  $r_0/a$  for the DBW2 action using the tree-level improved definition of the force.

in Fig. 3.5.

In [99] the value  $r_0/a = 5.24(3)$  for the DBW2 action at  $\beta = 1.04$  is quoted. Our value differs about 3% from that one.

### 3.2.5 Scaling of $T_c r_0$

Once  $r_0/a$  at the given couplings is known, one can finally consider the renormalized quantity

$$r_0 T_c = \frac{1}{N_t} \frac{r_0}{a}(\beta_c), \quad (3.21)$$

which has a finite value in the limit  $a \rightarrow 0$  (while  $N_t \rightarrow \infty$ ).

The results for Iwasaki and DBW2 actions are given in Table 3.7, together with the values obtained using the Wilson action. Also in this case, we show both the results obtained with the naive and with the tree-level improved definition of the force. The error in  $T_c r_0$  is the quadratic sum of the error for  $r_0/a$  and the uncertainty in  $\beta_c$ , which can be translated to an uncertainty in  $r_0$  by using the parametrization formulas eq. (3.10), eq. (3.17), eq. (3.19), assuming that the coefficients in the fit are exact. In our evaluations the error for  $\beta_c$  and the uncertainty in  $r_0$  are roughly of the same order.

We expect that the leading lattice artefacts are of order  $a^2$ , such that the continuum limit is approached in the following way

$$T_c r_0 = T_c r_0|_{a=0} + s \cdot (a T_c)^2 + O(a T_c)^4. \quad (3.22)$$

**Figure 3.6:**  $T_c r_0$  for different actions. The  $x$  coordinates were slightly shifted for clarity.

The results for  $T_c r_0$ , together with the continuum extrapolation, are shown in Fig. 3.6.

For the Iwasaki action there is no appreciable difference between the results obtained with  $r_n$  and  $r_I$  and in both cases the data show better scaling properties in comparison to the Wilson action. Furthermore, the value obtained at  $N_t = 8$  is in full agreement with the continuum result evaluated through the Wilson action and hence the universality is confirmed; this supports the conclusion that the disagreement observed in  $T_c/\sqrt{\sigma}$  is indeed due to the difficulty in evaluating the string tension, particularly at small lattice spacings and it is necessary to set the scale through a more reliable quantity.

Also for the DBW2 action the scaling properties are improved, although only using  $r_I$  instead of  $r_{naive}$ , so that it is more difficult to make a statement about the lattice artifacts in this case.

A constrained fit of the form eq. (3.22) including the points with  $N_t \geq 6$  for Iwasaki and Wilson actions yields the continuum result (Fig. 3.7)

$$T_c r_0 = 0.7498(50). \quad (3.23)$$

At  $N_t = 6$  the Wilson action shows scaling violations for  $r_0 T_c$  of about 1.5%, while

**Figure 3.7:** Continuum extrapolation of  $T_c r_0$  for the Iwasaki and Wilson action, using the constrained fit eq. (3.22).

$T_c r_0$ :	Wilson	Iwas.( $r_n$ )	Iwas.( $r_I$ )	DBW2( $r_n$ )	DBW2( $r_I$ )
$N_t$					
3		0.7703(50)	0.7733(53)	0.8100(90)	0.7417(90)
4	0.7194(22)	0.7565(23)	0.7565(23)	0.7822(65)	0.7590(56)
6	0.7388(30)	0.7558(33)	0.7518(31)	0.7676(68)	0.7593(76)
8	0.7445(33)	0.7525(60)	0.7499(55)		
12	0.7464(44)				

**Table 3.7:** Results for  $T_c r_0$ .

they are 0.3% for the Iwasaki action.

For  $N_t = 4$  the discretization errors for the Wilson action increase to 4%, while for the Iwasaki action they remain small (0.6%).

In Fig. 3.6 we included also the results obtained with the FP action [50], which also show a good scaling within 1% even on coarse lattices corresponding to  $N_t = 3, 2$ . One has however to mention that for those lattices the determination of  $r_0/a$  contains large systematic uncertainties.

### 3.3 Scaling of $\alpha_{q\bar{q}}(\mu)$

Another interesting observable that can be used to test the scaling violations is the dimensionless coupling  $\alpha_{q\bar{q}}$  obtained from the force. Since in chapter 2 we evaluated

the force and the potential very precisely and performed the continuum extrapolation for those quantities, we can compare these results with our present determination of the force at finite lattice spacings for the Iwasaki and DBW2 actions at different distances  $r$ . We point out that we only determined the on-axis potential and hence we can not investigate violations of rotational invariance which would require the evaluation of off-axis quantities.

The coupling  $\alpha_{\text{q}\bar{\text{q}}}$  can be obtained from the force by the simple relation

$$\alpha_{\text{q}\bar{\text{q}}}(\mu) = \frac{3}{4}F(r)r^2, \quad \mu = \frac{1}{r}. \quad (3.24)$$

Figure 3.8 shows  $\alpha_{\text{q}\bar{\text{q}}}$  in the continuum limit and the results obtained with the Iwasaki and DBW2 actions at the largest  $\beta$  at our disposal. For the Iwasaki action no appreciable difference in the results obtained with  $r_n$  and  $r_{\text{I}}$  can be seen, while for the DBW2 action the discrepancy becomes large at small distances.

At large enough distances one obtains a good scaling in the coupling, and one does not observe scaling violation within the statistical errors. At small  $r/r_0$  one sees deviations from the continuum limit, as one can observe in Fig. 3.9, where only the short distance region is considered. The deviations can be estimated to about 2% for the Iwasaki action at  $r \sim 0.4r_0$ ; for the DBW2 action they amount to 4% at  $r \sim 0.4r_0$  if one uses  $r_n$  to define the force, and reach even 40% by employing  $r_{\text{I}}$ . This fact shows that the adoption of a tree level improved definition of the force does not guarantee success in reducing the lattice artifacts, above all for RG actions, which are overcorrected at tree level.

**Figure 3.8:**  $\alpha_{q\bar{q}}$  at finite lattice spacing for Iwasaki and DBW2 action compared with the continuum result. The solid line represents the 3-loop RG perturbative prediction of the running coupling as obtained in sect. 2.2; the dashed lines correspond to the uncertainty on the  $\Lambda$  parameter in eq. (2.36).

**Figure 3.9:**  $\alpha_{q\bar{q}}$  at finite lattice spacing for Iwasaki and DBW2 action compared with the continuum result in the short distance region.

## Chapter 4

# Scaling properties of RG actions: the glueball masses

Osterwalder and Seiler showed in 1978 [63] that in strongly coupled lattice gauge theory the lowest eigenstate of the Hamiltonian above the vacuum has a mass  $m$ , which is usually called mass gap. This result can not be obtained in the framework of perturbation theory: on the classical level the gauge field theory does not contain any mass term and is scale invariant. Furthermore, the gluon propagator remains massless to all orders of the perturbative expansion. This state is hence of purely non-perturbative nature (in the infinite-volume limit) and states with higher masses are to be expected too. If the masses scale near the continuum limit according to

$$am = C_m \exp\left(-\frac{1}{2b_0g_0^2}\right) (b_0g_0^2)^{-b_1/(2b_0^2)} \{1 + O(g_0^2)\}, \quad (4.1)$$

it means that they are proportional to the  $\Lambda$  parameter and hence the corresponding states survive in the continuum limit and the quantized gauge theory contains massive physical states. The existence of these states, called glueballs, has been predicted in [109].

Being of non-perturbative nature, Monte Carlo simulations on the lattice provide a powerful tool to evaluate the glueball masses; they were indeed among the first quantities that have been computed on the lattice [110].

Since the theoretical discovery of the glueballs, which constitutes one of the most fascinating predictions of the pure gauge sector of QCD, also the experimental search started. There is indeed an evidence for the existence of exotic glueballs or hybrid particles consisting of quarks with gluonic excitation. For a review on the light meson spectroscopy see [111]. The difficult task here is to distinguish the glueball states from the background of mesons, which have the same quantum numbers. For this reason the exotic glueballs, e.g  $0^{+-}$ ,  $1^{-+}$ , are particularly interesting because due to their quantum numbers they can not mix with conventional meson states. Lattice QCD investigations [112, 113, 114, 115], were addressed to study the effects of dynamical quarks and glueball-meson mixing on the glueball spectrum from lattice QCD.

Apart from the physical relevance, the mass of the lightest ( $0^{++}$ ) glueball is particularly interesting since several calculations with the Wilson action [40, 41, 42, 43]

showed large lattice artefacts of about 40% at coarse lattice spacings  $a \simeq 0.15\text{fm}$  and still 20% at  $a \simeq 0.10\text{fm}$ . This quantity could hence in principle provide another stringent test on the scaling behavior of alternative gauge actions. It is desirable to check the discretization errors on several physical observables, since they can be quite different depending on which quantity we are considering.

As already pointed out since the first works, the calculation of glueball masses presents a lot of technical difficulties; due to the fact that these are quite large ( $m_G \geq 1.6\text{GeV}$ ), the signal in the correlation functions of the gluonic excitations decay fast and disappears in the noise.

Several smearing techniques were developed in order to suppress excited states and to be able to extract the masses at moderately large value of  $t$ . It turned out that these techniques are more efficient in the region of small lattice spacings, where one expects for this reason the determination of the glueball masses to be easier.

However, as already pointed out, one has to remember that in order to neglect finite size effects one has to consider a physical lattice extent  $L \gtrsim 3r_0$ , so that the simulations at small lattice spacing are very expensive and it is very difficult to reach a large statistics which is usually required for those calculations.

A possible solution to this problem can be to use anisotropic lattices [116], where the resolution in the time direction is finer than in the space directions  $a_t \ll a_s$ , and hence one can follow the signal over a larger range of time slices. Morningstar and Peardon [117, 118] applied this method to evaluate the glueball spectrum below 4GeV in the pure SU(3) gauge theory and improved the previous determinations of the glueball masses remarkably. In this chapter we will present the calculation of  $am_{0^{++}}$  and  $am_{2^{++}}$  for RG actions in the range of lattice spacings  $0.11\text{fm} \lesssim a \lesssim 0.17\text{fm}$ , and then make use of the knowledge of  $r_0/a$  to build the renormalized quantities  $r_0m_{0^{++}}$  and  $r_0m_{2^{++}}$ .

Our intention here is not to have a more precise determination of the glueball masses than what can be found in the literature and indeed our total errors on the measurements are quite sizeable; we will focus on the investigation of discretization effects and on possible further difficulties that can arise in the extraction of the masses from correlation functions.

## 4.1 Glueball states

Physical states in the vacuum sector of the Hilbert space of lattice gauge theory can be obtained by applying gauge invariant operators to the vacuum. As particular candidates one can take space-like Wilson loops lying in the  $x_0 = 0$  timeslice in the fundamental representation eq. (2.2), considered as multiplicative operators on wave functions. The simplest choice is the plaquette eq. (1.4)

$$W_{ij}^{1 \times 1}(\vec{x}), \quad (4.2)$$

where  $\vec{x} = (x_1, x_2, x_3)$ ,  $i, j \in \{1, 2, 3\}$ .

Applied to the vacuum the operator yields a state

$$|\tilde{\Psi}_{ij}(\vec{x})\rangle = \{W_{ij}^{1 \times 1}(\vec{x}) - \langle 0|W_{ij}^{1 \times 1}(\vec{x})|0\rangle\} |0\rangle, \quad (4.3)$$

where the projection onto the vacuum itself has been subtracted.

Eigenstates of the momentum operator are formed by Fourier transformation

$$|\Psi_{ij}(\vec{k})\rangle = L^{-3/2} \sum_{\vec{x}} e^{i\vec{x}\cdot\vec{k}} |\tilde{\Psi}_{ij}(\vec{x})\rangle. \quad (4.4)$$

If one is interested in the determination of masses it is sufficient to consider zero momentum states, denoted by

$$|\Psi_{ij}\rangle \equiv |\Psi_{ij}(\vec{0})\rangle. \quad (4.5)$$

We assume that the continuum limit of SU(3) lattice gauge theory exists and their rotational invariance is restored: the spin of a state is then characterized by the unitary irreducible representations of  $SO(3)$ , for bosonic states.

On a cubic lattice the rotation symmetry is broken down to the cubic group  $O$ ; the eigenstates of the Hamiltonian have hence to be classified according to the unitary irreducible representations of  $O$ .

For the first application of the representation theory of the cubic group to lattice gauge theory one can refer to the paper by Berg and Billoire [119].

The cubic group contains 24 elements, corresponding to the permutations of the four space diagonals of a cube. There are five irreducible representations, denoted by  $A_1, A_2, E, T_1$  and  $T_2$ , which have dimensions 1,1,2,3 and 3. Since the cubic group is a subgroup of  $SO(3)$ , any representation  $D_J$  of  $SO(3)$  for a state of spin  $J$  will induce a representation on the group  $O$ , the so-called subduced representation  $D_J^O$ . It will in general no longer be irreducible and can be decomposed into the irreducible representations of  $O$ . Up to  $J = 4$  one finds

$$D_0^O = A_1 \quad (4.6)$$

$$D_1^O = T_1 \quad (4.7)$$

$$D_2^O = E \oplus T_2 \quad (4.8)$$

$$D_3^O = A_2 \oplus T_1 \oplus T_2 \quad (4.9)$$

$$D_4^O = A_1 \oplus E \oplus T_1 \oplus T_2. \quad (4.10)$$

For example, a spin 2 particle is described in the continuum by a quintuplet of degenerate states; on the lattice the quintuplet is split into a doublet  $E$  and a triplet  $T_2$ . At finite lattice spacing one expects a mass splitting between the two representations, so that  $m_E \neq m_{T_2}$ . By approaching the continuum limit the ratio  $m_E/m_{T_2}$  will converge to one in order to restore the full Euclidean rotational symmetry. For the Wilson action we expect that the leading discretization corrections in mass ratios are of order  $a^2$ ; for other lattice formulations this is no more obvious and in fact with our data we will not be able to give conclusions on the form of the lattice artefacts in the specific range of lattice spacings that we have considered.

Given a lattice operator which transforms according to some irreducible representation  $R$  of the cubic group, by applying it to the vacuum one obtains a state

$$|\Psi_R\rangle = \sum_{\alpha} c_{\alpha}^R |\Psi_{\alpha}\rangle, \quad (4.11)$$

where  $|\Psi_{\alpha}\rangle$  are eigenstates of the Hamiltonian. In the continuum limit any  $|\Psi_{\alpha}\rangle$  belongs to some spin  $J$  multiplet, so that  $|\Psi_R\rangle$  contains various spins  $J$ . A spin  $J$  can occur in this superposition only if  $R$  is contained in  $D_J^O$ .

At this point the important assumption is that the lowest spin contained in  $R$  will belong to the lowest mass and will therefore dominate the correlation functions. The representations of the cubic group, their dimensions and the lowest spin content are summarized in Table 4.1.

In addition to the symmetry associated with the cubic group, there are two discrete symmetries: the total space reflection and the charge conjugation. The eigenvalues of the space reflections correspond to the parity  $P = \pm 1$ ; the cubic group combined with space reflection forms the group  $O_h = O \times \mathbb{Z}_2$ , which contains 48 elements.

The charge conjugation corresponds for the Wilson loops to the complex conjugation, and its eigenvalues are  $C = \pm 1$ . The states belonging to an irreducible representation of the lattice symmetry are then labeled by

$$|\Psi\rangle = |J^{PC}\rangle. \quad (4.12)$$

## 4.2 Irreducible representations of the cubic group on Wilson loops

Spatial Wilson loops, being gauge invariant operators acting on the vacuum, create physical states like eq. (4.5). Here we will consider the space-like Wilson loops up to length 8, for which all irreducible representations of  $O_h$  have been constructed [119]. The loops are shown in Fig. 4.1.

The first simple rule that one can easily obtain is that real parts of the Wilson loops have  $C$ -parity  $C = +1$ , imaginary parts have  $C = -1$ . Every Wilson loop corresponding to a path of length  $L$  can be represented by an  $L$ -tuple

$$(\hat{f}_1, \dots, \hat{f}_L), \quad \text{with} \quad \sum_{i=1}^L \hat{f}_i = 0, \quad (4.13)$$

where  $\hat{f}_i$  are unit vectors corresponding to the space-like coordinates in positive and negative directions ( $\pm\hat{1}, \pm\hat{2}, \pm\hat{3}$ ). The equivalence class corresponding to  $(\hat{f}_1, \dots, \hat{f}_L)$  will be denoted by  $[(\hat{f}_1, \dots, \hat{f}_L)]$  and will contain  $L$ -tuples which are equivalent up to cyclic permutations.

Under  $C$ -parity one has the transformation

$$C[(\hat{f}_1, \dots, \hat{f}_L)] = [(-\hat{f}_L, \dots, -\hat{f}_1)], \quad (4.14)$$

so that the combinations

$$[(\hat{f}_1, \dots, \hat{f}_L)]_{\pm} = [(\hat{f}_1, \dots, \hat{f}_L)] \pm [(-\hat{f}_L, \dots, -\hat{f}_1)] \quad (4.15)$$

R	Dimension	Lowest spin $J$
$A_1$	1	0
$A_2$	1	3
$E$	2	2
$T_1$	3	1
$T_2$	3	2

**Table 4.1:** Irreducible representations of the cubic group  $O$ .

are even and odd under  $C$ -parity respectively.

On operators of fixed shape we generate a representation  $\mathcal{M}$  of  $O_h$  by means of

$$\mathcal{M}_g[(\hat{f}_1, \dots, \hat{f}_L)]_{\pm} \doteq [(\mathcal{M}_g \hat{f}_1, \dots, \mathcal{M}_g \hat{f}_L)]_{\pm}, \quad \forall g \in O_h, \quad (4.16)$$

where  $\mathcal{M}_g$  is the matrix corresponding to the group element  $g$  in the fundamental representation. Excluding the  $C$ -parity, the dimension  $d$  of the generated representation will be less or equal than 48, which is the order of the group  $O_h$  and which will correspond to the number of different spatial orientations of the given shape. In the second column of Table 4.2 the dimensions  $d$  of the generated representations on every loop shape are listed.

The irreducible contents of the representation  $\mathcal{M}$  can be determined by means of the so-called character relation. The characters are a set of quantities which are the same for all equivalent representations. For finite groups they uniquely determine the representations up to equivalence, providing in particular a complete specification of the irreducible representations contained in a given representation. In general we will have

$$\mathcal{M} = n_1 \Gamma^1 \oplus n_2 \Gamma^2 \oplus \dots, \quad (4.17)$$

where  $\Gamma^p$  are the irreducible representations listed in Table 4.1 and  $n_p$  is the multiplicity of  $\Gamma^p$  in  $\mathcal{M}$ .

For fixed  $C$ -parity one finds

$$n_p = \frac{1}{48} \sum_{\mathcal{C}} n_{\mathcal{C}} \chi(\mathcal{C}) \chi^p(\mathcal{C}), \quad (4.18)$$

where the sum goes over all classes of conjugate elements,  $n_{\mathcal{C}}$  is the number of elements in the class  $\mathcal{C}$  and  $\chi(\mathcal{C})$ ,  $\chi^p(\mathcal{C})$  are the characters of  $\mathcal{M}$ ,  $\Gamma^p$  respectively; for matrix representations the character is given by the trace of the corresponding matrix and is the same for all elements in a given conjugacy class. The results for the  $C$ -parity plus representations are given in Table 4.2.

### 4.3 Wave functions of glueball operators

In order to perform a Monte Carlo calculation of the glueball masses, for each irreducible representation one has to calculate an orthonormal basis explicitly. This procedure involves the character projection operator, which is defined in general by

$$\mathcal{P}^p = \frac{d_p}{g} \sum_{T \in \mathcal{G}} \chi^p(T)^* P(T), \quad (4.19)$$

Figure 4.1: Wilson loops up to length 8.

where  $p$  labels the irreducible representations  $\Gamma^p$  of dimension  $d_p$  of a finite group of coordinate transformations  $\mathcal{G}$  of order  $g$ ,  $\chi^p(T)$  being the character of  $T \in \mathcal{G}$  in  $\Gamma^p$  and  $P(T)$  the unitary operator in the Hilbert space of the coordinate transformations  $T \in \mathcal{G}$ .

$\mathcal{P}^p$  projects out of a function  $\phi$  of the Hilbert space the sum of all the parts transforming under  $\Gamma^p$ . Having chosen a function  $\phi$  such that  $\mathcal{P}^p\phi$  does not vanish identically, one constructs  $P(T)(\mathcal{P}^p\phi)$  for each  $T \in \mathcal{G}$ . Each of these are linear combinations of the  $d_p$  basis functions of  $\Gamma^p$ . From these functions one extracts  $d_p$  linearly independent functions and applies the Gram-Schmidt orthogonalization to obtain a set of orthonormal functions of the irreducible representation.

What we practically did is to construct from a loop prototype for each shape by respecting the following rule: one builds the path first going in 1-, then on 2- and finally, if necessary, in 3-direction. From this reference orientation all others can be generated by applying the group elements of  $O_h$  in a given order, taking care not to generate orientations that are equivalent up to translations. Once all the independent orientations were created, we formed the orthonormal basis systems for each irreducible representation by taking the related coefficients from the literature [119, 120].

As example we can consider the single plaquette operator (loop shape #1), for which the orthogonal wave functions are listed in Table 4.3, with the following convention. The numbers in each row denote the contribution of the specific orientation to the wave function in question; the three positive orientations of the single plaquette can be labeled as  $O_{12}$ ,  $O_{13}$  and  $O_{23}$ . The wave function associated to the irreducible representation  $A_1^{++}$  will be constructed by forming

$$O^{A_1^{++}} = O_{12} + O_{13} + O_{23}, \quad (4.20)$$

while the  $E^{++}$  functions are

$$O_1^{E^{++}} = 2O_{12} - O_{13} - O_{23} \quad (4.21)$$

$$O_2^{E^{++}} = O_{13} - O_{23}. \quad (4.22)$$

## 4.4 Simulation details

For the numerical simulation, we followed essentially the method proposed by [50]. We performed a test simulation using the standard Wilson action for  $\beta = 6.0$  on a  $16^4$  lattice, for which results can be found in the literature.

We decided to concentrate on  $m_{0^{++}}$  and  $m_{2^{++}}$  by measuring the masses in the representations  $A_1^{++}$ ,  $E^{++}$  and  $T_2^{++}$ . The  $m_{0^{++}}$  is particularly interesting for our purpose to investigate the lattice artefacts on RG actions since these turn out to be quite sizeable for the Wilson action.

For our test simulation we measured all 22 loop shapes up to length 8 and formed the wave functions corresponding to  $A_1^{++}$ ,  $E^{++}$  and  $T_2^{++}$  as explained in the previous sections. Our timeslice observable at time  $t$  is

$$S_n^R(t) = \frac{L^{-3/2}}{K} \sum_{\vec{x}} \sum_{i=1}^{d_n} c_n^{iR} \text{Re} W_n^i(\vec{x}, t), \quad n = 1, \dots, 22, \quad (4.23)$$

where the coefficient  $c_n^{iR}$  are taken from the literature [119, 120], the sum over  $i$  indicates the sum over all  $d_n$  orientations of a given shape  $n$  and  $K$  is a suitable

**Table 4.3:** Orthogonal wave functions of the irreducible operators that can be built from the plaquette.

normalization constant.

As for the calculation of the potential, a smearing procedure is necessary in order to improve the overlap with the ground state. We applied the smearing operator eq. (2.54) to every space-like link; for  $\beta = 6.0$  we found that  $M = 4$ ,  $n_l = (5, 10, 15, 20)$  was a reasonably good choice for the smearing levels.

Then we build the correlation matrices <sup>1</sup>

$$C_{kl}^R(t) = \langle S_k^R(t) S_l^R(0) \rangle_c = \langle S_k^R(t) S_l^R(0) \rangle - \langle S_k^R(t) \rangle \langle S_l^R(0) \rangle, \quad (4.24)$$

for  $R = A_1^{++}, E^{++}, T_2^{++}$ . The indices  $k, l$  assume  $(22 \times M)$  values, where  $M$  is the number of smearing levels.

We expect that

$$\langle S_k^R(t) S_l^R(0) \rangle_c = \langle \Psi_k^R | e^{-Ht} | \Psi_l^R \rangle = \sum_{\alpha} \langle \Psi_k^R | \Psi_{\alpha} \rangle \langle \Psi_{\alpha} | \Psi_l^R \rangle e^{-m_{\alpha}(R)t}, \quad (4.25)$$

where  $|\Psi_{\alpha}\rangle$  are eigenstates of the Hamiltonian. At large  $t$  the lowest mass  $m_0(R)$  dominates; it belongs to a glueball state which in the continuum limit will have the lowest spin contained in the representation  $R$ .

Starting from our large basis, we analyzed the signal/noise ratio of the different operators in order to eliminate those which introduce large noise and to reduce the correlation matrix to a set of well measurable operators. It is important not to include noisy operators in the analysis performed through the variational method, because they could introduce numerical instabilities in the generalized eigenvalue problem.

We considered the effective masses evaluated from the diagonal elements of the correlation matrix eq. (4.24)

$$m_{eff}^{lR} = -\log \left( \frac{C_{ll}^R(t)}{C_{ll}^R(t-1)} \right) \quad (4.26)$$

<sup>1</sup>Notice that the vacuum subtraction is required only in the  $A_1^{++}$  channel, since it has the same quantum numbers as the vacuum.

and took the relative error as quality of the corresponding operator.

We found general agreement in the classification of the "bad" operators with [120].

Our final choice for the operators to measure was then

$$A_1^{++} : \#2, \#5, \#7, \#8, \#10, \#12, \#14 \quad (4.27)$$

$$E^{++} : \#2, \#5, \#7, \#10, \#12, \#14 \quad (4.28)$$

$$T_2^{++} : \#7, \#12, \#14, \quad (4.29)$$

where for  $E^{++}$  and  $T_2^{++}$  channels we took respectively 2 and 3 orthogonal projections for each shape. For each operator we then considered all  $M$  smearing levels.

One has to keep in mind that our choice contains a certain degree of arbitrariness, since the behavior of the different operators may depend on the considered lattice spacing. We did not perform a systematic study and we assumed that this choice is reasonable for each value of the coupling and also for the Iwasaki and DBW2 actions.

The simulation parameters for our new Monte Carlo simulations are listed in Table 4.9. Measurements were taken after a number of sweeps between three and five.

## 4.5 Analysis details

For the extraction of glueball masses from the correlation matrices eq. (4.24) variational techniques are necessary. Due to the violation of physical positivity for the RG actions (appendix B), the variational method is mathematically not well founded, at least not at very small  $t_0$ , where one would like to apply it. The statistical errors are indeed drastically increasing with  $t$  and already at  $t = 4a$  the signal in the correlation function eq. (4.24) is lost in noise.

We decided to adopt the following procedure: first we solved the generalized eigenvalue problem

$$C(t_1)v_\alpha(t_1, t_0) = \lambda_\alpha C(t_0)v_\alpha(t_1, t_0), \quad (4.30)$$

with  $t_0 = 0$ ,  $t_1 = a$ . Then we projected the correlation matrices to the space of eigenvectors corresponding to the  $N$  eigenvalues which satisfy the condition <sup>2</sup>

$$\lambda_\beta > \epsilon, \quad \beta = 1, \dots, N, \quad (4.31)$$

where  $\epsilon$  is an adjustable (small) parameter. So the reduced matrix is obtained by <sup>3</sup>

$$C_{ij}^N(t) = (v_i(t_1, t_0), C(t)v_j(t_1, t_0)), \quad i, j = 1, \dots, N. \quad (4.32)$$

By choosing  $\epsilon$  appropriately in eq. (4.31) one hopes to get rid of most of the unphysical modes caused by negative and very small eigenvalues.

Then one can apply the variational method to the reduced matrix

$$C^N(t)w_\beta(t, t_0) = \lambda_\beta(t, t_0)C^N(t_0)w_\beta(t, t_0). \quad (4.33)$$

<sup>2</sup>in [50] the direct eigenvalues and eigenvectors of  $C(t_0)$  are considered, instead of the generalized one. We have tried both possibilities and found consistent results.

<sup>3</sup>The index  $R$  for the representation is now omitted.

The effective glueball mass can be read off directly from the largest eigenvalue corresponding to the lowest energy <sup>4</sup>

$$m_{eff}(t) = -\log\left(\frac{\lambda_0(t, t_0)}{\lambda_0(t-a, t_0)}\right). \quad (4.34)$$

or, alternatively one can project again  $C^N$  to the subspace corresponding to the lowest eigenvalue

$$C^1(t) = (w_1, C^N(t)w_1), \quad (4.35)$$

where  $w_1 = w_1(t_0 + a, t_0)$ ; then one evaluates the glueball masses by

$$m_{eff}(t) = -\log\left(\frac{C^1(t)}{C_1(t-a)}\right). \quad (4.36)$$

We tested that these two different evaluation yield results which are compatible within the statistical errors.

We chose  $\epsilon$  in eq. (4.31) so that the reduced matrix had dimension between 2 and 5. We applied the same procedure also for  $t_0 = a$ ,  $t_1 = 2a$  in eq. (4.30), but due to the fact that the statistical fluctuations are already quite large one has to start from the beginning from a reduced number of operators in order to be able to solve the generalized eigenvalue problem.

We decided to extract the glueball masses by taking our effective mass at  $t = 3a$  for the small  $\beta$  regime and  $t = 4a$  for the large value of the coupling at our disposal. For the RG actions we performed numerical simulations up to  $L = 16$ , with a minimum lattice spacing  $a \sim 0.1$  fm; in this sense we are quite far away from the continuum limit and we will not be able to perform a continuum extrapolation of the results, but on the other hand this is the regime of lattice spacings that have been used for simulations with dynamical fermions and hence it is desirable to obtain informations about the discretization errors in this region.

The figures 4.2,4.3 show the effective masses in the  $A_1^{++}$  channel computed by using eq. (4.34) (filled squares) and eq. (4.36) (empty squares) for the Iwasaki and the DBW2 action, with  $t_0 = 0$ . For the largest value of  $\beta$ , which are more precise, we show also the results obtained with  $t_0 = a$  (filled triangles). As for the potential, one notices also in this case the presence of negative contributions in the correlation functions due to unphysical states; the situation here is somehow more drastic since one has to discard for this reason the small  $t$  region but on the other hand the errors increase very rapidly and one is forced to extract the glueball mass at  $t = 3-4a$ . The results can then be affected by systematic errors that can not be easily estimated. In the plots we have indicated with the dotted lines the range in which we decided to take the mass. The statistical errors were evaluated by using a jackknife procedure. Concerning the determination of the  $m_{2^{++}}$  we observed that the signal for the  $E^{++}$

---

<sup>4</sup>Due to the periodic boundary conditions in the time-direction, the correlation matrix eq. (4.24) describes not only the correlation  $C(t)$ , but also  $C(T-t)$ , where  $T$  is the lattice time-extent. Therefore one would expect  $C(t) \sim A(e^{-mt} + e^{-m(T-t)})$ . If one assumes that  $T$  is much larger than the value of  $t$  at which we are able to evaluate the mass, one can neglect the contribution from  $(T-t)$ . For our largest lattice spacing ( $T = 10a$ ) we included this corrections and check that they are irrelevant for the measurement of the glueball masses.

channel is usually worse than for the  $T_2^{++}$  and the errors on the effective masses are very large already at  $t = 3a$ . For this reason we decided to use  $m_{T_2^{++}}$  as estimate of  $m_{2^{++}}$  at finite lattice spacing.

The figures 4.4,4.5 show the effective masses for the  $T_2^{++}$  channel. The determination of the masses is more problematic than the  $A_1^{++}$  case; in particular for the largest coupling one can observe that at  $t = 4a$  the errors are too large to have a significant measurement of the mass. We decided hence to extract the mass at  $t = 3a$ , taking care that this value is compatible with the one at  $t = 4a$  within the statistical errors.

## 4.6 Results

In Table 4.5, Table 4.6 the results for the masses in lattice units are reported. For the smallest  $\beta$  for the Iwasaki action, it was not possible to obtain a reliable evaluation of the mass in the  $T_2^{++}$  channel.

The renormalized quantities  $r_0 m_G$  are reported in Table 4.7, Table 4.8; due to the fact that the errors on  $am_G$  are quite large (between 8% and 9% for  $A_1^{++}$  and between 10% and 20% for  $T_2^{++}$ ), the difference which arises by choosing  $r_I$  or  $r_n$  is in this case much smaller than the total uncertainty; we have reported however both results in the table. For  $\beta = 2.2423$  we had no direct measurement of  $r_0/a$  and we used the interpolation formula eq. (3.17) to evaluate it.

Figure 4.6 shows the results for  $r_0 m_{0^{++}}$  as function of  $(a/r_0)^2$ , displaying only the results obtained with  $r_n$ . For the comparison we included the results for FP action [50] and several calculations performed with the Wilson action [116, 121, 40].

The continuum values available in the literature are listed in Table 4.4 and have been taken from [50] for the FP action and from [122] for the Wilson action, where the results of [116, 121, 40] have been expressed in units of  $r_0$ .

The interpretation of our results is not very clear, also due to the large errors.

In any case, we want to stress that our determination can be seen at least as an upper limit for  $m_{0^{++}}$  and  $m_{2^{++}}$ . We expect that at the values of  $t/a$  at which we extracted the masses, the effects of positivity violations have already disappeared; this assumption is justified by our study based on perturbation theory and our estimation of  $t_{min}$  eq. (B.35).

For this reason we believe that possible systematic uncertainties on the glueball masses could only be due to the presence of excited states and hence could affect our measurement only in such a way that the real values of  $m_{0^{++}}$ ,  $m_{2^{++}}$  are lower with respect to our determination.

At lattice spacings  $a \sim 0.15$  fm we notice a improvement of the RG actions with respect to the Wilson action; comparing with the continuum limit we find no significant discrepancy both for DBW2 and Iwasaki action, while for the Wilson action one finds 30 – 40% deviation.

At lattice spacing  $a \sim 0.1$  fm we find on the other hand large lattice artefacts for RG actions: the result obtained with the Iwasaki action is practically compatible with the one calculated through the plaquette action at the same lattice spacing, while for the DBW2 action it is even further away from the continuum limit.

If one considers our measurement as upper limit, one could conclude that the RG

**Figure 4.2:** The effective masses for the  $A_1^{++}$  channel, evaluated with Iwasaki action, at different lattice spacings. The filled and empty squares corresponds to respectively to eq. (4.34) and eq. (4.36) with  $t_0 = 0$ . For  $\beta = 2.5206$ , the filled triangles correspond to eq. (4.34) with  $t_0 = a$ .

**Figure 4.3:** The effective masses for the  $A_1^{++}$  channel, evaluated with DBW2 action, at different lattice spacings. The filled and empty squares corresponds to respectively to eq. (4.34) and eq. (4.36) with  $t_0 = 0$ . For  $\beta = 0.9636$ , the filled triangles correspond to eq. (4.34) with  $t_0 = a$ .

**Figure 4.4:** The effective masses for the  $T_2^{++}$  channel, evaluated with Iwasaki action, at different lattice spacings. The filled and empty squares corresponds to respectively to eq. (4.34) and eq. (4.36) with  $t_0 = 0$ .

**Figure 4.5:** The effective masses for the  $T_2^{++}$  channel, evaluated with DBW2 action, at different lattice spacings. The filled and empty squares corresponds to respectively to eq. (4.34) and eq. (4.36) with  $t_0 = 0$ .

improved actions are not able to cure the problem of large lattice artefacts for the  $0^{++}$  glueball mass. At very small lattice spacings one expects that the dominant lattice artefacts are of order  $a^2$ ; for the Wilson action this is indeed well confirmed by the numerical results in the range  $a \lesssim 0.17\text{fm}$ , as one can see in Fig. 4.6.

For alternative actions there is no reason a priori to observe the same behavior: while at small lattice spacings the  $O(a^2)$  should in any case be the dominant one, at larger  $a$  it is possible that lattice artefacts are governed by higher orders ( $O(a^4)$  and higher).

We have indeed already observed deviations from  $O(a^2)$  behavior in RG actions for the quantity  $T_c r_0$  and even already for the force computed at tree level (chapter 3). With our results it is not possible to investigate how the continuum limit is approached, because one should evaluate the glueball masses at smaller lattice spacing and this was beyond the purpose of this work. The evident problem shown in our plot is that a continuum extrapolation of the form

$$r_0 m_{0^{++}} = r_0 m_{0^{++}}|_{a=0} + s \times \left(\frac{a}{r_0}\right)^2 \quad (4.37)$$

of the data obtained with the RG action in the considered range of lattice spacings would lead to results which are rather different from the expected continuum limit. One has however to remember that the extraction of the glueball masses is for RG actions particularly difficult and the systematic errors could be underestimated.

In Fig. 4.7 we report our results for  $r_0 m_{2^{++}}$ ; for this particular observables the calculation performed with the Wilson action do not show significant lattice artefacts.

At our smallest lattice spacing we do not observe a deviation from the results obtained with the Wilson action; one has however to notice that our errors are too

large to make any conclusive statement.

For our largest lattice spacing the results with the Wilson action are not available (there are only known results with anisotropic lattices [118]) and it is indeed difficult to have a reliable estimation of the mass also in our case: we decided to show however our results, even with the very large error bars.

From our computation one can not deduce if for  $r_0m_{2^{++}}$  the RG actions show significant discretization errors and further investigations are needed to clarify the issue.

## 4.7 Open questions

As already mentioned, RG action have been indicated by some Collaborations [37, 98, 99] as best candidates to be used in the simulations with dynamical fermions.

In view of these next simulations, it is important to have under control the properties of alternative gauge actions by testing their features, the universality and the discretization errors for several physical quantities.

This motivated our investigations and requires further studies on this subject.

An important point to stress is that in full lattice QCD it can happen that the features of different gauge actions are modified, also depending on which formulation of fermions on the lattice is adopted.

For example, the JLQCD and CP-PACS collaborations have used a  $O(a)$  formulation of the fermionic action, the so-called Sheikholeslami-Wohlert (clover) action [32], which is based on the Symanzik approach (see chapter 1). In order to achieve the improved action one has to add a counterterm such that the order  $a$  term in the action of the effective continuum theory is canceled. For the improved action one thus obtains

$$S = S_{Wilson} + a^5 \sum_x c_{sw} \bar{\psi}(x) \frac{i}{4} \sigma_{\mu\nu} \hat{F}_{\mu\nu}(x) \psi(x), \quad (4.38)$$

where  $S_{Wilson}$  corresponds to the Wilson fermionic action<sup>5</sup> and  $\hat{F}_{\mu\nu}$  is a lattice representation of the gluon field tensor.

The coefficient  $c_{sw}$  in eq. (4.38) has to be tuned appropriately. For example, for simulations with 2 flavors of dynamical fermions, the CP-PACS collaboration used the mean field  $O(a)$  improved definition for the fermionic action together with the Iwasaki gauge action [37], while the JLQCD collaboration used non-perturbative  $O(a)$  improved Wilson fermion together with the plaquette gauge action [123].

It was observed [124] that for  $N_f = 3$  simulations with  $O(a)$ -improved Wilson fermions and plaquette gauge action one finds an unexpected first order phase transition at zero-temperature.

The investigations indicate that this phase transition is a lattice artefact restricted to strong coupling regions ( $\beta \lesssim 5.0$ ). This phenomenon spoils the possibility to perform a continuum extrapolation of physical quantities unless one considers only couplings in the region  $\beta \gtrsim 5.0$ .

The interesting fact is that this transition disappears if one adopts alternative gauge actions, like Iwasaki or tadpole-improved Symanzik action, or alternatively if one uses the unimproved Wilson fermionic action ( $c_{sw} = 0$ ) with the plaquette gauge action.

A plausible scenario is that the clover term added in eq. (4.38) produces a term in the adjoint representation of the gauge fields with a positive coupling.

It is indeed known that pure SU(3) lattice gauge theory containing fundamental and adjoint representations of the gauge fields undergoes a first order phase transition

---

<sup>5</sup>Fermions on the lattice are described by Grassmann variables  $\psi$ ,  $\bar{\psi}$  defined on the lattice sites. There are several possibilities to define the lattice action associated to fermions, leading to different properties. The so-called Wilson action on the lattice can be written in the form  $S_{Wilson} = a^4 \sum_x \bar{\psi}(x) (D + m_0) \psi(x)$ , where  $m_0$  is the bare quark mass and  $D = \frac{1}{2} \{ \gamma_\mu (\nabla_\mu^* + \nabla_\mu) - a \nabla_\mu^* \nabla_\mu \}$  is the lattice Dirac operator.

for positive values of the adjoint coupling [125, 126, 127]. A simple way to construct a gauge action with an adjoint coupling would be to generalize the Wilson plaquette action in the following way:

$$S = \beta_F \sum_x \sum_{\mu < \nu} \left\{ 1 - \frac{1}{3} \text{Re} W_{\mu\nu}^{1 \times 1}(x) \right\} + \beta_A \sum_x \sum_{\mu < \nu} \left\{ 1 - \frac{1}{9} |W_{\mu\nu}^{1 \times 1}(x)|^2 \right\}, \quad (4.39)$$

where  $W^{1 \times 1}$  is the plaquette defined in eq. (1.4).

The resulting line of the first order phase transition with the location of the end-point for the gauge group SU(3) is shown in Fig. 4.8. The Wilson plaquette action corresponds to the line  $\beta_A = 0$ : it is located below the end point of the phase transition and hence it is safe to take the continuum limit along this line. If one would approach the continuum limit by crossing the transition line above this point, there would be discontinuities in the expectation values of Wilson loops and in glueball masses. In particular, at the point of intersection with the transition line the  $0^{++}$  glueball mass is expected to be zero.

The fact that for the Wilson action the lattice artefacts for  $m_{0^{++}}$  are large and the glueball mass in lattice units becomes small could then also be interpreted as the “influence” of the endpoint of the first order phase transition on the  $\beta_A = 0$  line corresponding to the Wilson action.

In order to test the validity of this scenario, one should add an adjoint term in the action and check how does it change the behavior of the  $O^{++}$  glueball masses.

An important test is also the computation of scalar glueball mass in full QCD<sup>6</sup>; recent results [128] are shown in Fig. 4.9. The SESAM [114] results have been obtained with Wilson gauge and fermion action, while UKQCD [115, 129] adopted  $O(a)$  Wilson improved fermions. The larger lattice spacing results show a significant reduction in the lightest scalar mass, as shown in Fig. 4.9.

It is very important to understand if it implies a lower scalar mass also in the continuum limit or if an enhanced  $O(a^2)$  correction might be present.

A useful study would be to repeat these investigations with alternative gauge actions, starting for example by locating the position of the end point of the first order phase transition; it is interesting to know if it lies closer or further away from the  $\beta_A = 0$  line with respect to the plaquette action.

From our calculation of the glueball masses with Iwasaki and DBW2 action one can not deduce any possible scenario and a systematic investigation which includes adjoint terms would be needed.

Discussing these open issues will be helpful to understand properties of full QCD on the lattice and choose an optimal combination of gauge and fermionic actions to perform reliable unquenched simulations.

---

<sup>6</sup>By inserting dynamical fermions in the theory, the mass eigenstates with  $0^{++}$  quantum numbers are not distinguished as “glueballs” or as “quark-antiquark” states; in general mixing will occur.

**Figure 4.8:** The phase diagram of SU(3) gauge theories in the fundamental-adjoint coupling space [130].

**Figure 4.9:** Plot from [128] for the value of mass of the  $0^{++}$  glueball state from quenched data [42, 41, 40, 118] and for the lightest scalar meson with  $N_f = 2$  flavours of dynamical quarks [114, 115, 129].

# Conclusions

The main object of the first part of this work was the potential between a static quark and antiquark in the pure SU(3) gauge theory. In particular, we concentrated on the question whether at short distances large non perturbative terms are present. To test this possibility we used both the potential and the force, which define two different renormalization schemes. The first step was to obtain a parameter-free perturbative prediction for these quantities from the Renormalization Group equation at two and tree loops; this was possible due to the fact that the  $\Lambda$  parameter is known from lattice studies [15] and the coefficients of the  $\beta$ -function have been calculated up to tree loops [53, 54, 20, 55, 56, 57].

Then we performed a numerical Monte Carlo simulation to evaluate potential and force non-perturbatively. In the pure gauge theory it was possible to compute these quantities over a large range of distances with high precision by considering two sets of lattices and matching them (in the continuum limit) in a region of overlap. By setting the length scales  $r_0$  and  $r_c$  we built renormalization group invariant quantities and we performed a continuum extrapolation of our results. At this stage we investigated the scaling violations and we were able to confirm Symanzik's picture of lattice artifacts. By comparing these results with the perturbative prediction we did not observe the presence of large non-perturbative terms. Furthermore, we remarked that different renormalization schemes have different convergence properties and the scheme defined through the force is in this sense more appropriate: here perturbation theory works remarkably well up to  $\alpha_{q\bar{q}} \sim 0.3$ , while for the potential only up to  $\alpha_{\bar{v}} \sim 0.15$ .

This result confirms what can already be argued from the apparent “convergence” by comparing the two- and three-loops expansions for the running coupling in the two schemes; the fact that the perturbative coupling defined through the potential fails in describing non-perturbative data is due the restricted domain of applicability of perturbation theory for this scheme rather than a signal of non-expected terms.

Although the situation in full QCD is much more complicated due to presence of different mass scales, this study may be a guideline for future investigations and applications of perturbation theory.

We then compared our results with the bosonic string model, which is expected to describe the long-distance properties [26] of the theory. We observed a surprising good agreement with the next-to-leading order prediction [27, 28] of the effective theory already at 0.4fm, where in principle the validity of the string picture is questionable.

By including a higher order correction estimated in another work [29] we observed that at large distances the agreement with the non-perturbative data is improved,

while at intermediate distances it is deteriorated. This fact is not surprising since we are dealing with asymptotic expansions and it could indicate that the agreement at intermediate distances is rather accidental. However we want to remark that we evaluated the potential only up to  $\sim 0.8\text{fm}$ , but a deep understanding of the string nature of the strong interactions requires the investigation at larger distances, where the statistical errors are usually very large. With the help of the numerical techniques introduced in [64] is now possible to reach an higher precision and hence it will be possible to perform stringent tests, also on the spectrum of excited states.

The second part of this work was dedicated to the study of scaling and universality properties of gauge actions alternative to the plaquette formulation; in particular we concentrated our attention on the Iwasaki and DBW2 actions, which contain also rectangular ( $1 \times 2$ ) loops and have been formulated by using Renormalization Group arguments.

Our main purpose was to test the universality and the scaling behavior for some relevant physical observable: we chose in particular the deconfinement temperature  $T_c$  and the mass of the glueballs  $0^{++}$  and  $2^{++}$ . The first issue that we faced was the setting of a suitable scale to build renormalized dimensionless quantities. As already pointed out in previous studies it is important to use a quantity which can be measured with good precision and which is not subjected to uncontrolled systematic errors; the intermediate length  $r_0$  had been introduced with this purpose and turned out to be a good choice.

We performed new numerical simulations at several lattice spacings to compute  $r_0/a$ , which was up to now not available on the literature for the Iwasaki and DBW2 actions. In the analysis of our results we remarked that for these actions the physical positivity is violated [39]: in particular, negative contributions are expected in Euclidean correlation functions for small time. By investigating the location of the poles in the propagator at tree level, we evaluated for different actions the value of  $t_{min}$  such that for  $t \gg t_{min}$  these unphysical contributions are expected to disappear. We discussed the implications for the extraction of physical observables, in particular for the applicability of the variational method, which is founded per definition on physical positivity.

Interesting features of these actions could also be learnt by studying the force at tree level: we noticed that RG actions are “overcorrected” at tree level and that beside the leading lattice artifacts of order  $a^2$ , also higher powers are expected to be important.

With our determinations of  $r_0/a$  we then formed the quantity  $T_c r_0$  and we compared the results at different lattice spacings with the ones obtained with the plaquette Wilson action. For the Iwasaki action we observed a reduction of the lattice artifacts, while for the DBW2 action the situation is less clear since the results depend quite strongly on which definition of the force at finite lattice spacing is adopted. The important result is that universality is confirmed for this particular observable; in previous calculations the quantity  $T_c/\sqrt{\sigma}$  was used and a discrepancy in the continuum extrapolations between Iwasaki and Wilson actions was observed [38]. Our result exclude a violation of the universality and seem to confirm that this disagreement was generated by the problems related with the extraction of the string tension

$\sigma$  and hence by the choice of the quantity used to set the scale.

With our results we were able to give a parametrization formula which describes  $r_0/a$  in the range  $2.1551 \leq \beta \leq 2.7124$  for the Iwasaki action and  $0.75696 \leq \beta \leq 1.04$  for the DBW2 action, which can be useful for future applications.

We checked the scaling of RG actions also on the running coupling extracted from the force by comparing the results at our smallest lattice spacing with the continuum results obtained in the first part of the work. As expected, at sufficiently large distances, we found no significative deviation, while at small  $r/r_0$  we observed a difference of 2% for the Iwasaki action and 4 – 10% for the DBW2 action, depending also in this case on the definition of the force at finite lattice spacings.

Finally we computed the glueball masses for the  $0^{++}$  and  $2^{++}$  states. We started by selecting a basis of "good" operators from Wilson loops up to length eight, using the signal/noise ratio as criterion for the choice.

For the evaluation of the glueball masses the violation of physical positivity is even more problematic than for the potential, since one can not avoid to use variational techniques. We analyzed our data by truncating the correlation matrices to suitable subspaces where the presence of unphysical states is supposed to be reduced. We build the quantities  $r_0 m_{0^{++}}$  and  $r_0 m_{2^{++}}$ ; our final results are however affected by large errors; additional studies and numerical techniques are necessary to deduce clear conclusions on the lattice artefacts for these observables. However, by considering our determinations as upper limit for the glueball masses at different lattice spacings, one could conclude that the RG actions are not able to significantly reduce the discretization errors for  $m_{0^{++}}$  with respect to the plaquette action.

Further investigations on the properties of RG actions could be very useful to clarify this question more definitively as well as further open questions, also in view of the future unquenched simulations.

# Appendix A

## Numerical results

In this appendix the numerical results for potential and force at finite lattice spacing are collected, for different gauge actions.

### A.1 Wilson action

The tables [A.2](#) and [A.4](#) report the data for potential and force at finite lattice spacing (chapter [2](#)) for the Wilson action. For the couplings  $5.7 \leq \beta \leq 6.4$  we took the data from Guagnelli et. al. [[73](#)], while in the range  $6.57 \leq \beta \leq 6.92$  the results were obtained from our new numerical simulations.  $r_I$  and  $d_I$  define the tree-level improved observables and are expressed in eq. ([2.52](#)), eq. ([2.84](#)).

### A.2 RG actions

The tables [A.5](#) and [A.6](#) report the data for the potential and the force evaluated at finite lattice spacing with Iwasaki and DBW2 actions, which has been used in chapter [3](#). Also in this case  $r_I$  defines the tree-level improved force. For the potential only the naive definition is reported.

# Appendix B

## Transfer matrix and Hamiltonian formalism

The Hamiltonian formalism constitutes a very useful framework in order to extract physical observables from the exponential decay of Euclidean correlation functions. In this appendix the transfer matrix formulation will be reviewed, with a particular attention to the improved actions, where the violation of physical positivity at cutoff-energies can be a problem for the extraction of physical observables.

In the formulation of eq. (1.8), lattice gauge theories are represented as a statistical mechanical system with partition function  $Z$  and thermal averages  $\langle \mathcal{O} \rangle$ . The transfer matrix provides an equivalent representation of the model as a quantum mechanical system with a Hilbert space  $\mathcal{H}$ , a Hamiltonian operator  $\mathbb{H}$  and linear operators  $\hat{\mathcal{O}}$  corresponding to the observables  $\mathcal{O}$ .

We will now assume that the Euclidean space-time lattice  $\Lambda$  is finite, with  $T \times L \times L \times L$  points and we take periodic boundary conditions for the gauge fields

$$U(x + aT\hat{\nu}, \mu) = U(x, \mu), \quad \nu = 0 \tag{B.1}$$

$$U(x + aL\hat{\nu}, \mu) = U(x, \mu), \quad \nu > 0. \tag{B.2}$$

In this appendix we will set  $a = 1$  for simplicity.

### B.1 Wilson action

We denote the set of links that are completely contained in the time slice  $x_0 = t$  by  $B_t$ ; those links which connect the time slices  $x_0 = t+1$  and  $x_0 = t$  form the set  $B_{t+1,t}$ . Let  $b$  be a link connecting the lattice points  $x$  and  $(x + \hat{\mu})$  and  $U(b) \equiv U(x, \mu)$ ; then the links belonging to  $B_t$  and  $B_{t+1,t}$  are denoted by

$$U_t \equiv U(b), \quad b \in B_t, \tag{B.3}$$

$$U_{t+1,t} \equiv U(b), \quad b \in B_{t+1,t}. \tag{B.4}$$

The Wilson action can be written as

$$S = \sum_t L [U_{t+1}, U_{t+1,t}, U_t], \tag{B.5}$$

where

$$L[U_{t+1}, U_{t+1,t}, U_t] = \frac{1}{2}L_1[U_{t+1}] + \frac{1}{2}L_1[U_t] + L_2[U_{t+1}, U_{t+1,t}, U_t]. \quad (\text{B.6})$$

The first two terms in eq. (B.6)

$$L_1[U_t] = -\frac{\beta}{N} \sum_{\vec{x}} \sum_{k < l} \text{Re } W_{kl}^{1 \times 1}(x)|_{x_0=t} \quad (\text{B.7})$$

are the contribution of space-like plaquettes on a time slice, while

$$L_2[U_{t+1}, U_{t+1,t}, U_t] = -\frac{\beta}{N} \sum_{\vec{x}} \sum_k \text{Re } W_{k0}^{1 \times 1}(x)|_{x_0=t} \quad (\text{B.8})$$

represents the contribution of time-like plaquettes between two time slices. The plaquette  $W_{\mu\nu}^{1 \times 1}(x)$  is defined in eq. (1.4).

We then consider wave functions  $\Psi[U_t]$  depending on the link variables on a certain time slice; these describe states belonging to different charged sectors depending on how they transform under gauge transformations. In particular, we will consider gauge invariant wave functions, which correspond to the vacuum sector

$$\Psi[U'_t] = \Psi[U_t], \quad (\text{B.9})$$

where  $U'_t$  and  $U_t$  are gauge-equivalent.

A convenient way to define a scalar product of two given wave functions  $\Psi$  and  $\Phi$  is given by

$$(\Phi, \Psi) = \int D[U_t] \Phi[U_t]^* \Psi[U_t], \quad (\text{B.10})$$

with

$$D[U_t] = \prod_{b \in B_t} dU(b). \quad (\text{B.11})$$

The Hilbert space  $\mathcal{H}$  corresponds to the space of all gauge invariant functions with finite norm,

$$(\Psi, \Psi) < \infty. \quad (\text{B.12})$$

The transfer matrix  $\mathbb{T}$  [131] is an integral operator acting on  $\mathcal{H}$  via

$$(\mathbb{T}\Psi)[U_{t+1}] = \int D[U_t] K[U_{t+1}, U_t] \Psi[U_t], \quad (\text{B.13})$$

where  $K$  is an integral kernel

$$K[U_{t+1}, U_t] = \int D[U_{t+1,t}] \exp\{-L[U_{t+1}, U_{t+1,t}, U_t]\}. \quad (\text{B.14})$$

From these considerations follows that

$$Z = \int D[U] e^{-S[U]} = \text{tr} \{\mathbb{T}^T\}, \quad (\text{B.15})$$

where “tr” indicates the trace in the Hilbert space.

The Euclidean correlation functions  $\langle A(x)B(y)\dots \rangle$  of local, gauge invariant fields  $A(x), B(y)\dots$  can be given in a quantum mechanical interpretation. In particular, if these fields are polynomials of the gauge field variables  $U_t$  at a fixed time  $t$ , we may associate an operator  $\hat{A}(\vec{x})$  through

$$(\hat{A}(\vec{x})\Psi)[U_t] = A(0, \vec{x})\Psi[U_t]. \quad (\text{B.16})$$

For  $x_0 = t$ ,  $0 \leq x_0 \leq T$  we have

$$\langle A(x)A(0) \rangle = \frac{1}{Z} \text{tr} \left\{ \mathbb{T}^{T-t} \hat{A}(\vec{x}) \mathbb{T}^t \hat{A}(\vec{0}) \right\}. \quad (\text{B.17})$$

Similar formulas hold for higher correlation functions. The transfer matrix  $\mathbb{T}$  turns out to be a bounded, self-adjoint positive operator with a completely discrete spectrum (for finite  $L$ ).

All eigenvalues of  $\mathbb{T}$  are then strictly positive and the maximal eigenvalue  $\lambda_0$  is not degenerate. Thus one can define the Hamiltonian

$$\mathbb{H} = -\ln \frac{\mathbb{T}}{\lambda_0}, \quad (\text{B.18})$$

which is a self-adjoint operator in  $\mathcal{H}$ . For  $T \rightarrow \infty$  the two-point function eq. (B.17) then assumes the form

$$\langle A(x)A(0) \rangle = \langle 0 | \hat{A}(\vec{x}) e^{-t\mathbb{H}} \hat{A}(\vec{0}) | 0 \rangle, \quad (\text{B.19})$$

which is also called *spectral representation* and establishes the exponential decay of Euclidean two-point functions, which is the basis of the extraction of physical observables from lattice QCD.

## B.2 Improved actions

We now consider actions containing not only the plaquette term, but also other classes of loops  $\mathcal{C}$  included in a real gauge invariant and orientation independent function of the ordered product of link variables along  $\mathcal{C}$ . These include both Lüscher-Weisz and RG improved actions as particular cases. One can prove that for those actions it is still possible to construct a transfer matrix [39]. Restricting to actions of kind eq. (1.13), one can notice that in the temporal gauge,  $U(x, 0) = 1$ , the associated field equations assume the form of a fourth-order difference equation in the time coordinate  $x_0$ . One has then to define a transition amplitude to go from a given gauge configuration on a pair of consecutive equal time hyperplanes to some other gauge fields on a later pair of hyperplanes. For the wave function  $\Psi$  one then makes the ansatz

$$\Psi = \Psi[U_{t+1}, U_{t+1,t}, U_t]. \quad (\text{B.20})$$

A gauge invariant scalar product is now

$$(\Phi, \Psi) = \int D[U_{t+1}] D[U_{t+1,t}] D[U_t] \Phi[U_{t+1}, U_{t+1,t}, U_t]^* \Psi[U_{t+1}, U_{t+1,t}, U_t]. \quad (\text{B.21})$$

The transfer matrix can be defined in analogy to the Wilson case as transition amplitude between fields configurations defined on two consecutive pairs of hyperplanes  $(B_t, B_{t+1})$  and  $(B_{t+1}, B_{t+2})$ , and one can argue that the properties eq. (B.15) and eq. (B.16) are satisfied.

But, unlike the Wilson case, one finds that  $\mathbb{T}$  is no longer hermitian; rather, one obtains

$$\mathbb{T}^\dagger = \theta \mathbb{T} \theta, \quad (\text{B.22})$$

where

$$\theta \Psi[U_{t+1}, U_{t+1,t}, U_t] = \Psi[U_t, U_{t+1,t}^{-1}, U_{t+1}], \quad \theta^\dagger = \theta, \quad \theta^2 = 1. \quad (\text{B.23})$$

The spectrum  $\sigma(\mathbb{T})$  of  $\mathbb{T}$  can be defined as the set of complex numbers  $\lambda$ , for which the operator  $\lambda - \mathbb{T}$  has no bounded inverse. Further considerations [39] lead to the conclusion that spectral values always occur in pairs of complex conjugated numbers and there is a positive (non-degenerate) eigenvalue  $\lambda_0$  such that

$$\lambda_0 > |\lambda|, \quad \forall \lambda \in \sigma(\mathbb{T}), \quad \lambda \neq \lambda_0. \quad (\text{B.24})$$

The eigenfunction  $\Psi_{\lambda_0}$  may be interpreted as ground state wave function. Due to the violation of physical positivity, it is no longer possible to define an Hamiltonian operator and hence to write down the spectral representation eq. (B.19). For  $T \rightarrow \infty$  the two-point function eq. (B.17) takes the form

$$\langle A(x)A(0) \rangle = \lambda_0^{-t} \langle 0 | \theta \hat{A}(\vec{x}) \mathbb{T}^t \hat{A}(\vec{0}) | 0 \rangle, \quad (\text{B.25})$$

where  $|0\rangle \equiv |\Psi_{\lambda_0}\rangle$ , and in the limit  $t \rightarrow \infty$  one ends up with an asymptotic expansion

$$\langle A(x)A(0) \rangle \sim_{t \rightarrow \infty} \lambda_0^{-t} \sum_{\lambda \in \sigma(\mathbb{T}) \setminus \lambda_0} \lambda^t p_\lambda(t), \quad (\text{B.26})$$

where  $p_\lambda(t)$  is a polynomial of  $t$  with degree strictly less than a certain  $n_\lambda$ : usually  $n_\lambda = 1$  as in the hermitian case, but one can find examples where  $n_\lambda > 1$  for some  $\lambda$ . The eq. (B.26) establishes that connected two-point functions always decay exponentially at large times, but if the leading spectral value is not real and positive, the exponential factor is multiplied by an oscillating amplitude and contributions in the spectral decomposition with negative weight appear, as remnant of the positivity violation. This fact has been observed in the evaluation of the effective potential and effective masses for improved actions 3, 4 and can be a serious problem for the applicability of the variational method.

Nevertheless, one expects that physical positivity is recovered in the continuum limit; restricting ourself to the subspace  $\mathcal{H}_{phys}$  of the states with small energy with respect to the cutoff ( $\lambda/\lambda_0 \sim 1$ ), then the non-hermiticity of the transfer matrix can be eliminated by choosing a new scalar product relative to which  $\mathbb{T}$  becomes hermitian and physical positivity is then completely restored. For example

$$(\Phi, \Psi)_{new} = (\Phi, \theta \Psi)_{old} \quad (\text{B.27})$$

is not well defined on the full Hilbert space, but one expects that there exists a  $0 < \epsilon < 1$  such that independently of the cutoff the following properties hold:

- (i) all spectral values  $\lambda \in \sigma(\mathbb{T})$  with  $|\lambda| \geq \epsilon\lambda_0$  are real and positive;
- (ii)  $(\Psi, \Psi)_{new} > 0, \quad \forall \Psi \in \mathcal{H}_{phys}, \quad \Psi \neq 0.$

The existence of such  $\epsilon$  has not been rigorously proved, but is supported by perturbative calculations, which can be used to estimate a value of  $\epsilon$  by determining the location of unphysical poles in the propagator, as shown in the next section.

### B.2.1 Unphysical poles in the propagator

In [47] the propagator  $D_{\mu\nu}$  is evaluated to lowest order in  $g_0$  with covariant gauge fixing; it is defined by

$$\langle A_\mu^i(x) A_\nu^j(y) \rangle = \delta^{ij} \int_k e^{ik(x-y)} e^{i(k_\mu - k_\nu)/2} D_{\mu\nu}(k), \quad (\text{B.28})$$

where  $A_\mu(x)$  is related to the link variables by

$$U(x, \mu) = e^{-A_\mu(x)}$$

and the momenta integration corresponds to

$$\int_k = \prod_{\mu=0}^3 \int_{-\pi}^{\pi} \frac{dk_\mu}{2\pi}.$$

We are now referring to the case  $L = \infty$ , so that the momenta take continuous values in the Brillouin zone.

Eq. (B.28) can be rewritten in the form

$$D_{\nu\tau}(k) = (\hat{k}^2)^{-2} \left[ \alpha \hat{k}_\nu \hat{k}_\tau + \sum_\sigma (\hat{k}_\sigma \delta_{\tau\nu} - \hat{k}_\tau \delta_{\sigma\nu}) A_{\tau\sigma}(k) \hat{k}_\sigma \right], \quad (\text{B.29})$$

where  $\alpha$  is the gauge parameter,  $\hat{k}_\mu = 2 \sin(k_\mu/2)$  and  $A_{\mu\nu}$  is independent of  $\alpha$  and satisfies the following properties:

1.  $A_{\mu\mu} = 0, \quad \forall \mu;$
2.  $A_{\mu\nu} = A_{\nu\mu};$
3.  $A_{\mu\nu}(k) = A_{\mu\nu}(-k);$
4.  $A_{\mu\nu}(0) = 1, \quad \mu \neq \nu.$

$A_{\mu\nu}$  has the general form

$$A_{\mu\nu} = \frac{f(\hat{k})}{D}, \quad (\text{B.30})$$

where

$$D = \sum_\mu \hat{k}_\mu^4 \prod_{\nu \neq \mu} q_{\mu\nu} + \sum_{\mu > \nu, \rho > \tau, \{\rho, \tau\} \cup \{\mu, \nu\} = \emptyset} \hat{k}_\mu^2 \hat{k}_\nu^2 q_{\mu\nu} (q_{\mu\rho} q_{\nu\tau} + q_{\mu\tau} q_{\nu\rho}), \quad (\text{B.31})$$

and the explicit form of  $f(\hat{k})$  can be found in [47] and will not reported here. The denominator of eq. (B.29) is then given by

$$\Delta = D(\hat{k}^2)^2 = \quad (\text{B.32})$$

$$(\hat{k}^2)^2 \left( \sum_{\mu} \hat{k}_{\mu}^4 \prod_{\nu \neq \mu} q_{\mu\nu} + \sum_{\mu > \nu, \rho > \tau, \{\rho, \tau\} \cup \{\mu, \nu\} = \emptyset} \hat{k}_{\mu}^2 \hat{k}_{\nu}^2 q_{\mu\nu} (q_{\mu\rho} q_{\nu\tau} + q_{\mu\tau} q_{\nu\rho}) \right),$$

where  $q_{\mu\nu}$  satisfies the properties (1)-(4) and in our specific form of the action takes the form

$$q_{\mu\nu} = (1 - \delta_{\mu\nu})[1 - c_1(\hat{k}_{\mu}^2 + \hat{k}_{\nu}^2)], \quad (\text{B.33})$$

$c_1$  being the coefficient of the  $1 \times 2$  planar loops term in the action eq. (1.34). Then eq. (B.32) becomes

$$\begin{aligned} \Delta = & \left( \hat{k}^2 - c_1 \sum_{\mu} \hat{k}_{\mu}^4 \right) \left[ \hat{k}^2 - c_1 \left( (\hat{k}^2)^2 + \sum_{\mu} \hat{k}_{\mu}^4 \right) + \right. \\ & \left. \frac{1}{2} c_1^2 \left( (\hat{k}^2)^3 + 2 \sum_{\mu} \hat{k}_{\mu}^6 - \hat{k}^2 \sum_{\mu} \hat{k}_{\mu}^4 \right) \right] - 4c_1^3 \sum_{\mu} \hat{k}_{\mu}^4 \prod_{\nu \neq \mu} \hat{k}_{\nu}^2. \end{aligned} \quad (\text{B.34})$$

In order to search for the poles of the propagator, one substitutes

$$k = (\hat{k}_1, \hat{k}_2, \hat{k}_3, iw)$$

and looks for solutions of the equation  $\Delta = 0$  scanning the whole Brillouin zone. For the plaquette action  $c_1 = 0$  one finds the usual result

$$w = \pm \sqrt{\hat{k}_1^2 + \hat{k}_2^2 + \hat{k}_3^2}$$

while for general  $c_1$  one expects complex conjugated solutions

$$w = \Re(w) \pm i\Im(w) = w(\hat{k}_1, \hat{k}_2, \hat{k}_3).$$

Numerical investigations showed that the condition  $\Im(w) = 0$  (for *all* solutions at a given momentum) defines the equation  $f(\hat{k}_1, \hat{k}_2, \hat{k}_3) = 0$  which represents a compact 3-dimensional object. In Fig. B.1 the 2-dimensional intersection with the plane  $\hat{k}_3 = 0$  is plotted for several values of  $c_1$  corresponding to different actions. For our numerical studies, we discretized the Brillouin zone in finite intervals that could be made arbitrarily small.

In the region enclosed by the curve one has  $\Im(w) = 0$ , while outside  $\Im(w) \neq 0$ . The Fig. B.2 represents the distribution of the poles; by scanning the Brillouin zone and varying the intervals of the momenta, one reaches the conclusion that there exists a maximal value of  $\Re(w)$ , which is related to  $c_1$  by

$$w_{max} = 2 \operatorname{arcsinh} \left( \frac{1}{2\sqrt{-2c_1}} \right) = \begin{cases} 2.063 & \text{Symanzik, tree level} \\ 1.162 & \text{Iwasaki} \\ 0.588 & \text{DBW2} \end{cases}$$

**Figure B.1:** The curves defined by the condition  $\Im m(w) = 0$  in the  $\hat{k}_3 = 0$  plane. Inside the curve  $\Im m(w) = 0$ , while outside  $\Im m(w) \neq 0$ .

**Figure B.2:** Distribution of the poles for different actions, scanning the Brillouin zone.

such that for  $w < w_{max}$  the imaginary part  $\Im(w)$  vanishes.

The value of  $w_{max}$  yields an estimate of  $\epsilon$  defined above through the simple relation

$$\epsilon = e^{-w_{max}} = \begin{cases} 0.127 & \text{Symanzik, tree level} \\ 0.313 & \text{Iwasaki} \\ 0.555 & \text{DBW2} \end{cases}$$

Evaluating observables from exponential decays of correlation functions, one expects the presence of unphysical states unless  $t \gg t_{min}$ , where  $t_{min}$  in lattice units is given by

$$t_{min} = \frac{1}{w_{max}} = \begin{cases} 0.484 & \text{Symanzik, tree level} \\ 0.860 & \text{Iwasaki} \\ 1.702 & \text{DBW2} \end{cases} \quad (\text{B.35})$$

This fact has to be taken into account in the extraction of physical observables from correlation functions evaluated with RG actions, and in general with every action which contains not only plaquette terms. In particular this restricts the applicability of the variational method.

One has to remember that our estimation of the unphysical poles has been performed in perturbation theory and one can not exclude a priori that at large coupling  $g_0$  the numerical value of  $\epsilon$  can be larger than what we found.

# Appendix C

## Evaluation of the 3-dimensional lattice propagator in coordinate space

An efficient method to calculate the lattice propagator in coordinate space is proposed in [132]. It is based on a recursion relation which allows to express the propagator as linear function of its values near the origin. In that paper, the 4-dimensional case is discussed; it is straightforward to apply the same method in 3 dimensions. We use lattice units,  $a = 1$ , in this appendix and restrict the attention to the plaquette Wilson action.

### C.1 Lattice 3-dimensional propagator.

The 3-dimensional scalar propagator in the coordinate space satisfies the Laplace equation

$$-\Delta G(\vec{x}) = \begin{cases} 1 & \text{if } \vec{x} = 0 \\ 0 & \text{otherwise.} \end{cases} \quad (\text{C.1})$$

where the lattice Laplacian is given by

$$\Delta = \sum_{j=1}^3 \nabla_j^* \nabla_j, \quad (\text{C.2})$$

and  $\vec{x} = (x_1, x_2, x_3)$ .

The forward and backward lattice derivatives are defined through

$$\nabla_j f(\vec{x}) = f(\vec{x} + \hat{j}) - f(\vec{x}), \quad \nabla_j^* f(\vec{x}) = f(\vec{x}) - f(\vec{x} - \hat{j}), \quad (\text{C.3})$$

where  $\hat{j}$  denotes the unit vector in direction  $j$ .

In the continuum limit, which here coincides with the limit  $|\vec{x}| \rightarrow \infty$ , we expect that the propagator converges to  $4\pi|x|$ , which is the Green function of the continuum Laplacian on  $\mathbb{R}^3$ .

## C.2 Recursion relation

The first step to obtain a recursion relation is the observation that

$$(\nabla_j^* + \nabla_j)G(\vec{x}) = x_j H(\vec{x}), \quad (\text{C.4})$$

where

$$H(\vec{x}) = \int_{-\pi}^{+\pi} \frac{d^3 k}{(2\pi)^3} e^{i\vec{k}\cdot\vec{x}} \ln(\hat{k}^2) \quad (\text{C.5})$$

is independent of the direction  $j$  and

$$\hat{k}^2 = \sum_{j=1}^3 \hat{k}_j^2, \quad \hat{k}_j = 2 \sin(k_j/2). \quad (\text{C.6})$$

Summing over  $k$  and using eq. (C.1) one obtains

$$H(\vec{x}) = \frac{2}{\rho} \sum_{j=1}^3 [G(\vec{x}) - G(\vec{x} - \hat{j})]. \quad (\text{C.7})$$

with  $\rho = \sum_{j=1}^3 x_j$ .

This expression can be used to eliminate  $H(\vec{x})$  in eq. (C.4), giving

$$G(\vec{x} + \hat{j}) = G(\vec{x} - \hat{j}) + 2 \frac{x_j}{\rho} \sum_{i=1}^3 [G(\vec{x}) - G(\vec{x} - \hat{i})] \quad (\text{C.8})$$

which is valid only for the points with  $\rho \neq 0$ .

Because of isotropy, we can restrict our attention to the points  $\vec{x}$  with  $x_1 \geq x_2 \geq x_3 \geq 0$ . In this region eq. (C.8) is a recursion relation which can be used to express  $G(\vec{x})$  as a linear combination of the values of the Green function at the corners of the unit cube,

$$G(0, 0, 0), \quad G(1, 0, 0), \quad G(1, 1, 0), \quad G(1, 1, 1). \quad (\text{C.9})$$

This four initial values are not independent; from eq. (C.1) at  $\vec{x} = 0$

$$G(0, 0, 0) - G(1, 0, 0) = \frac{1}{6} \quad (\text{C.10})$$

follows directly. Another relation can be deduced in the following way: first one can observe that eq. (C.8) becomes one-dimensional along the lattice axes. Defining

$$g_1(n) = G(n, 0, 0), \quad g_2(n) = G(n, 1, 0), \quad g_3(n) = G(n, 1, 1),$$

and using the lattice symmetries, one finds

$$g_1(n+1) = 6g_1(n) - 4g_2(n) - g_1(n-1), \quad (\text{C.11})$$

$$g_2(n+1) = \frac{2n}{n+1} [3g_2(n) - g_1(n) - g_3(n)] - \frac{n-1}{n+1} g_2(n-1), \quad (\text{C.12})$$

$$g_3(n+1) = \frac{2n}{n+2} [3g_3(n) - 2g_2(n)] - \frac{n-2}{n+2} g_3(n-1). \quad (\text{C.13})$$

Next one notices that

$$I(n) = (n-1)g_1(n) + 2ng_2(n) + (n+1)g_3(n) - ng_1(n-1) - 2(n-1)g_2(n-1) - (n-2)g_3(n-1) \quad (\text{C.14})$$

is an invariant of the recursion relation, that is

$$I(n+1) = I(n)$$

for  $n \geq 1$ .

The value of  $I$  can be worked out in the limit  $n \rightarrow \infty$ , where

$$g_j(n) = \frac{1}{4\pi n} + O(1/n^2), \quad \text{for } j = 1, 2, 3,$$

yielding  $I = 0$ . Setting  $n = 1$ , eq. (C.14) gives

$$3G(1, 1, 0) + 2G(1, 1, 1) - G(0, 0, 0) = 0. \quad (\text{C.15})$$

Thus from the four initial values two can be eliminated using eq. (C.10) and eq. (C.15) and the propagator can be written in the form

$$G(\vec{x}) = r_1(\vec{x})G(0, 0, 0) + r_2(\vec{x})G(1, 1, 0) + r_3(\vec{x}), \quad (\text{C.16})$$

where the coefficients  $r_1, r_2, r_3$  are rational numbers that can be computed recursively from eq. (C.8).

### C.3 Numerical computation of $G(\vec{x})$

From eq. (C.16) one obtains the initial conditions for  $r_1, r_2, r_3$  :

$$r_1(0, 0, 0) = 1, \quad r_1(1, 1, 0) = 0 \quad (\text{C.17})$$

$$r_2(0, 0, 0) = 0, \quad r_2(1, 1, 0) = 1 \quad (\text{C.18})$$

$$r_3(0, 0, 0) = 0, \quad r_3(1, 1, 0) = 0. \quad (\text{C.19})$$

Eq. (C.10), eq. (C.15) give

$$r_1(1, 0, 0) = 1, \quad r_1(1, 1, 1) = \frac{1}{2} \quad (\text{C.20})$$

$$r_2(1, 0, 0) = 0, \quad r_2(1, 1, 1) = -\frac{3}{2} \quad (\text{C.21})$$

$$r_3(1, 0, 0) = -\frac{1}{6}, \quad r_3(1, 1, 1) = 0. \quad (\text{C.22})$$

The other coefficients  $r_1(\vec{x}), r_2(\vec{x}), r_3(\vec{x})$  can be calculated exactly using for example an algebraic programming language. We are then left with the task to compute numerically  $G(0, 0, 0)$  and  $G(1, 1, 0)$  with high accuracy. For this purpose we consider the lattice points  $x = (n, 0, 0)$  and  $y = (n, 1, 0)$ , where  $n$  is an adjustable integer. The numerical investigations show that the associated coefficients  $r_k(x)$  and  $r_k(y)$  are

**Table C.1:** Numerical values of the coefficients  $r_k(x), r_k(y)$  for  $n = 1, \dots, 7$ .

$n$	$r_1(x)$	$r_1(y)$	$r_2(x)$	$r_2(y)$	$r_3(x)$	$r_3(y)$
1	1	0	0	1	-0.17	0
2	5	-1.5	-4	4.5	-1	0.17
3	35	-14	-42	28.3	-6.5	2
4	261	-123.75	-361.3	219.75	-46	19.17
5	2026	-1091.2	-3005	1844.413	-346.17	174
6	16259.8	-9663.5	-25046.32	16000.9	-2727	1559.17
7	134186.8	-86122.9	-211276.52	141288.85	-22252.5	13968

rapidly growing, roughly proportional to  $10^{n-1}$  (see Table C.1). Solving eq. (C.16) for  $G(x)$  and  $G(y)$ , we obtain

$$G(1, 0, 0) = \frac{1}{C} \left\{ G(y) - G(x) \frac{r_1(y)}{r_1(x)} + \frac{r_3(x)r_1(y)}{r_1(x)} - r_3(y) \right\}, \quad (\text{C.23})$$

with

$$C = r_2(y) - \frac{r_2(x)r_1(y)}{r_1(x)}, \quad (\text{C.24})$$

and

$$G(0, 0, 0) = -\frac{r_2(x)}{r_1(x)} G(1, 1, 0) - \frac{r_3(x)}{r_1(x)}. \quad (\text{C.25})$$

The coefficients multiplying  $G(x)$  and  $G(y)$  are of order  $10^{-(n-1)}$  and can be neglected, obtaining

$$G(1, 0, 0) = \frac{1}{C} \left\{ \frac{r_3(x)r_1(y)}{r_1(x)} - r_3(y) \right\} + O(10^{-(n-1)}). \quad (\text{C.26})$$

This method is exponentially convergent and the error can be estimated well since the neglected terms are known.

By applying this technique one obtains

$$G(0, 0, 0) = 0.2527310098586630030260020266135701299\dots,$$

$$G(1, 0, 0) = 0.0551914336877373170165449460300639378\dots$$

# Acknowledgments

I would like to thank first of all Rainer Sommer for suggesting the argument of my thesis, for the competence and also for encouragement and constant support.

Thanks also to all people of DESY Zeuthen, in particular the theory/NIC group who created a stimulating and enjoyable working atmosphere and made these three years very fruitful.

I would like to thank Ulli Wolff, Peter Weisz and Urs Wenger for useful discussions and suggestions.

Special thanks to Francesco Knechtli for his help and the  $SU(2)$  code which was the starting point for our program, and to Marco Guagnelli and Hartmut Wittig for discussions and for providing the data generated in an earlier project.

Thank to Konrad-Zuse-Zentrum für Informationstechnik Berlin (ZIB) -in particular Hinnerk Stüben - and Forschungszentrum Jülich for providing CPU-resources on CRAY T3E machines and assistance.

Special thanks to Michele Della Morte, Chris Ford, Hiro Kawamura and Stephan Dürr for suggestions and comments related to the thesis.

I am grateful to every PhD student and postdoc with whom I shared not only the working time but also very nice moments of my life.

Finally I would like to thank my family and special friends: Elisa, Floriana, Lucia, Davide, Stefano, Marcella, Mauro, Vincenzo, Andrea, Alberto.

# Selbständigkeitserklärung

Hiermit erkläre ich, die vorliegende Arbeit selbständig ohne fremde Hilfe verfasst zu haben und nur die angegebene Literatur und Hilfsmittel verwendet zu haben.

Silvia Necco  
27.02.2003

# Lebenslauf

Name: Silvia Necco  
geboren am 26.05.74 in Torino (Italien)  
Nationalität: Italienisch  
7/1993 Abitur am “Liceo Scientifico Statale Albert Einstein”  
in Torino (Italien)  
10/1993 - 10/1999 Studium an der “Universitá degli Studi di Torino”  
in der Fachrichtung Physik  
seit 2/2000 Wissenschaftliche Mitarbeiterin beim  
Deutschen Elektronensynchrotron DESY, Zeuthen
